

Murray & Nadel's
Textbook of Respiratory
Medicine

Murray & Nadel's Textbook of Respiratory Medicine

SIXTH EDITION

Volume 1

Editor-in-Chief

V. Courtney Broaddus, MD

John F. Murray Distinguished Professor of Medicine
University of California San Francisco
Chief, Division of Pulmonary and Critical Care Medicine
San Francisco General Hospital
San Francisco, California

Editors

Robert J. Mason, MD

Cetalié & Marcel Weiss Chair in Pulmonary Medicine
Department of Medicine
National Jewish Health
Denver, Colorado;
Professor of Medicine
University of Colorado, Denver Health Sciences Center
Aurora, Colorado

Joel D. Ernst, MD

Director, Division of Infectious Diseases and Immunology
Jeffrey Bergstein Professor of Medicine
Professor of Medicine, Pathology and Microbiology
New York University School of Medicine
NYU Langone Medical Center
New York, New York

Talmadge E. King, Jr., MD

Julius R. Krevans Distinguished Professorship in Internal
Medicine
Chair, Department of Medicine
University of California San Francisco
San Francisco, California

Stephen C. Lazarus, MD

Professor of Medicine
Division of Pulmonary, Critical Care, Allergy, and Sleep
Medicine
Director, Training Program in Pulmonary and Critical Care
Medicine
Associate Director, Adult Pulmonary Laboratory
Senior Investigator, Cardiovascular Research Institute
University of California San Francisco
San Francisco, California

John F. Murray, MD, FRCP, DSc (Hon)

Professor Emeritus
Department of Medicine
University of California San Francisco
San Francisco General Hospital
San Francisco, California

Jay A. Nadel, MD, DSc (Hon), DLaw (Hon)

Professor of Medicine, Physiology, and Radiology
Division of Pulmonary and Critical Care Medicine
Cardiovascular Research Institute
University of California San Francisco
San Francisco, California

Arthur S. Slutsky, MD

Keenan Chair in Medicine
Professor of Medicine, Surgery and Biomedical Engineering
University of Toronto
Vice President (Research)
St. Michael's Hospital
Keenan Research Centre for Biomedical Science, Li Ka
Shing Knowledge Institute
Toronto, Ontario, Canada

Thoracic Imaging Editor

Michael B. Gotway, MD

Professor of Radiology
Mayo Clinic
Scottsdale, Arizona;
Clinical Associate Professor
Diagnostic Radiology/Biomedical Imaging and Pulmonary/
Critical Care Medicine
Department of Radiology and Biomedical Imaging
University of California San Francisco,
San Francisco, California;
Clinical Professor
University of Arizona College of Medicine
Phoenix, Arizona;
Adjunct Professor
Department of Biomedical Informatics
Arizona State University
Tempe, Arizona

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Murray and Nadel's textbook of respiratory medicine

Murray & Nadel's textbook of respiratory medicine / editor-in-chief, V. Courtney Broaddus ; editors, Robert J. Mason, Joel D. Ernst, Talmadge E. King Jr., Stephen C. Lazarus, John F. Murray, Jay A. Nadel, Arthur S. Slutsky ; thoracic imaging editor, Michael B. Gotway.—6th edition.

We dedicate this textbook to Dr. Julius H. Comroe, Jr., who was our mentor during the formative years of our professional development. Dr. Comroe was one of the truly great academicians of his generation. He was an investigator of exceptional merit, an educator whose influence was worldwide, and a medical statesman of exemplary integrity and vision. In dedicating this book, we acknowledge especially Dr. Comroe's scholarly contributions and his commitment to the importance of basic science in the solution of clinical problems.

Contributors

Lewis Adams, PhD

Professor of Physiology, School of Allied Health Sciences,
Griffith University, Gold Coast, Queensland, Australia
Ch. 29 Dyspnea

Dan Elie Adler, MD

Division of Pneumology, University Hospital of Geneva,
Geneva, Switzerland
Ch. 102 Noninvasive Ventilation

Alvar Agusti, MD, PhD, FRCPE

Professor, Hospital Clinic Universitat de Barcelona, Institut
Clinic del Torax, Barcelona, Spain
Ch. 43 COPD: Pathogenesis and Natural History

Evangelia Akoumianaki, MD

Intensive Care Unit, University Hospital of Geneva,
Geneva, Switzerland
Ch. 102 Noninvasive Ventilation

Anthony J. Alberg, PhD, MPH

Blatt Ness Professor, Department of Public Health
Sciences, Medical University of South Carolina,
Associate Director of Cancer Prevention and Control,
Hollings Cancer Center, Medical University of South
Carolina, Charleston, South Carolina
Ch. 52 Epidemiology of Lung Cancer

Kurt H. Albertine, PhD

Professor of Pediatrics, Adjunct Professor of Medicine,
and Neurobiology & Anatomy, University of Utah
School of Medicine, Editor-in-Chief, *The Anatomical
Record*, Salt Lake City, Utah
Ch. 1 Anatomy of the Lungs

Barbara D. Alexander, MD, MHS

Professor of Medicine and Pathology, Division of
Infectious Diseases, Director, Transplant Infectious
Disease Services, Head, Clinical Mycology Laboratory,
Duke University, Durham, North Carolina
Ch. 38 Opportunistic Mycoses

Paul H. Alfille, MD

Assistant Professor, Department of Anesthesia, Harvard
Medical School, Chief, Division of Neuro, Vascular and
Thoracic Anesthesia, Department of Anesthesia,
Critical Care and Pain Medicine, Massachusetts General
Hospital, Boston, Massachusetts
Ch. 27 Preoperative Evaluation

Devanand Anantham, MBBS, MRCP

Senior Consultant, Department of Respiratory and Critical
Care Medicine, Singapore General Hospital, Assistant
Professor of Medicine, Duke-NUS Graduate Medical
School, Singapore
Ch. 20 Ultrasonography

Douglas A. Arenberg, MD, FACP, FACC

Associate Professor of Medicine, Division of Pulmonary &
Critical Care Medicine, University of Michigan School
of Medicine, Ann Arbor, Michigan
Ch. 55 Metastatic Malignant Tumors
Ch. 56 Benign Lung Tumors

Najib T. Ayas, MD, MPH

Associate Professor of Respiratory Medicine, Head,
Division of Critical Care Medicine, University of British
Columbia, Vancouver, British Columbia, Canada
Ch. 5 Respiratory System Mechanics and Energetics

Aranya Bagchi, MBBS

Clinical Fellow in Anesthesia, Department of Anesthesia,
Critical Care and Pain Medicine, Harvard Medical
School, Massachusetts General Hospital, Boston,
Massachusetts
Ch. 27 Preoperative Evaluation

John Randolph Balmes, MD

Professor of Medicine, Division of Occupational and
Environmental Medicine, University of California San
Francisco, San Francisco, California; Professor of
Environmental Health Sciences, University of
California, Berkeley School of Public Health, Berkeley,
California
Ch. 74 Indoor and Outdoor Air Pollution

Niaz Banaei, MD

Assistant Professor, Departments of Pathology and
Medicine (Division of Infectious Diseases and
Geographic Medicine), Stanford University School of
Medicine, Stanford, California; Director, Clinical
Microbiology Laboratory, Stanford University Medical
Center, Palo Alto, California
Ch. 17 Microbiologic Diagnosis of Lung Infection

Christopher F. Barnett, MD, MPH

Assistant Professor of Medicine, Division of Cardiology,
University of California San Francisco, San Francisco,
California
Ch. 59 Pulmonary Hypertension due to Lung Disease

Robert P. Baughman, MD

Professor of Medicine, Department of Internal Medicine,
University of Cincinnati College of Medicine,
Cincinnati, Ohio
Ch. 66 Sarcoidosis

Margaret R. Becklake, MBBCh, MD

Professor Emeritus of Medical and Epidemiology,
Biostatistics and Occupational Health, McGill
University, Honorary Physician, McGill University
Health Centre, Montreal Chest Hospital Pavilion,
Montréal, Québec, Canada
Ch. 73 Pneumoconioses

Joshua O. Benditt, MD

Professor of Medicine, Division of Pulmonary and Critical
Care Medicine, University of Washington School of
Medicine, Director, Respiratory Care Services, University
of Washington Medical Center, Seattle, Washington
*Ch. 97 The Respiratory System and Neuromuscular
Diseases*

Neal L. Benowitz, MD

Professor of Medicine, Chief, Division of Clinical
Pharmacology and Experimental Therapeutics,
University of California San Francisco, Departments of
Medicine and Bioengineering and Therapeutic Sciences,
San Francisco General Hospital Medical Center, San
Francisco, California
Ch. 46 Smoking Hazards and Cessation

Nirav R. Bhakta, MD, PhD

Assistant Professor of Medicine, Pulmonary, Critical Care,
Allergy and Sleep Medicine, University of California San
Francisco, San Francisco, California
Ch. 41 Asthma: Pathogenesis and Phenotypes

Anant D. Bhave, MD

Associate Professor, Department of Radiology, University
of Vermont College of Medicine, Burlington, Vermont
*Ch. 19 Thoracic Radiology: Invasive Diagnostic
Imaging and Image-Guided Interventions*

Paul D. Blanc, MD, MSPH

Professor of Medicine, Endowed Chair in Occupational
and Environmental Medicine, University of California
San Francisco, Chief, Division of Occupational and
Environmental Medicine, UCSF Medical Center, San
Francisco, California
Ch. 75 Acute Responses to Toxic Exposures

Eugene R. Bleeker, MD

Thomas H. Davis Professor of Medicine, Division of
Pulmonary, Critical Care, Allergy and Immunologic
Diseases, Director, Center for Genomics and
Personalized Medicine Research, Wake Forest School of
Medicine, Winston-Salem, North Carolina
Ch. 45 Genetics in Asthma and COPD

Alfred A. Bove, MD, PhD

Professor Emeritus, Department of Medicine, Cardiology
Section, Temple University School of Medicine,
Philadelphia, Pennsylvania
Ch. 78 Diving Medicine

T. Douglas Bradley, MD

Professor and Director of the Division of Respiriology and
of the Centre for Sleep Medicine and Circadian
Neurobiology, University of Toronto, The Cliff Nordan
Chair in Sleep Apnea and Rehabilitation Research
Medicine, University Health Network Toronto Rehab
Foundation, and the University of Toronto, Director of
the Sleep Research Laboratories, University Health
Network Toronto Rehabilitation Institute and Toronto
General Hospital, Toronto, Ontario, Canada
Ch. 89 Central Sleep Apnea

Elisabeth Brambilla, MD, PhD

Professor of Pathology, INSERM/Université Joseph Fourier,
Department of Pathology, Hôpital Michallon, Grenoble,
France
Ch. 54 Rare Primary Lung Tumors

V. Courtney Broaddus, MD

John F. Murray Distinguished Professor of Medicine,
University of California San Francisco, Chief, Division
of Pulmonary and Critical Care Medicine, San
Francisco General Hospital, San Francisco, California
*Ch. 79 Pleural Effusion
Ch. 82 Pleural Tumors*

Laurent Brochard, MD

Interdepartmental Division Director for Critical Care
Medicine, Faculty of Medicine, University of Toronto,
Full Professor, Clinician Scientist, Department of
Medicine, Keenan Research Center for Biomedical
Science, Saint Michael's Hospital, Toronto, Ontario,
Canada
Ch. 102 Noninvasive Ventilation

Malcolm V. Brock, MD

Associate Professor of Surgery, Department of Surgery,
Division of Thoracic Surgery, Johns Hopkins Medical
Institutions, Baltimore, Maryland
Ch. 52 Epidemiology of Lung Cancer

Kevin K. Brown, MD

Professor and Vice Chair, Department of Medicine,
National Jewish Health, Denver, Colorado; Professor of
Medicine, University of Colorado, Denver School of
Medicine, Aurora, Colorado
Ch. 60 Pulmonary Vasculitis

Paul G. Brunetta, MD

Adjunct Associate Professor, Division of Pulmonary and
Critical Care Medicine, University of California San
Francisco, Fontana Tobacco Treatment Center, Mt. Zion
Medical Center, San Francisco, California
Ch. 46 Smoking Hazards and Cessation

Jacques Cadranel, MD, PhD

Professor of Respiratory Medicine, Université Pierre et Marie Curie, Department of Respiratory Medicine, CHU Paris Est-Hôpital Tenon, Paris, France
Ch. 54 Rare Primary Lung Tumors

Bartolome Celli, MD

Professor of Medicine, Harvard Medical School, Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, Massachusetts
Ch. 105 Pulmonary Rehabilitation

Edward D. Chan, MD

Professor of Medicine, University of Colorado Denver Anschutz Medical Campus, Staff Physician, Department of Medicine, Denver Veterans Affairs Medical Center, Staff Physician, Department of Academic Affairs, National Jewish Health, Denver, Colorado
Ch. 48 Bronchiectasis

Richard N. Channick, MD

Associate Professor of Medicine, Harvard Medical School, Director, Pulmonary Hypertension and Thromboendarterectomy Program, Massachusetts General Hospital, Boston, Massachusetts
Ch. 58 Pulmonary Hypertension

Jean Chastre, MD

Professor, Service de Réanimation Médicale, Institut de Cardiologie, Groupe Hospitalier Pitié-Salpêtrière, Paris, France
Ch. 34 Ventilator-Associated Pneumonia

Guang-Shing Cheng, MD

Assistant Professor of Medicine, Division of Pulmonary and Critical Care Medicine, University of Washington School of Medicine, Assistant Member, Clinical Research Division, Fred Hutchinson Cancer Research Center, Seattle, Washington
Ch. 83 Mediastinal Tumors and Cysts
Ch. 84 Pneumomediastinum and Mediastinitis

Kelly Chin, MD, MSCS

Director, Pulmonary Hypertension Program, Internal Medicine, Pulmonary Division, UT Southwestern, Dallas, Texas
Ch. 58 Pulmonary Hypertension

Kian Fan Chung, MD, DSc, FRCP

Professor of Respiratory Medicine, Head of Experimental Studies Medicine, National Heart & Lung Institute, Imperial College London, Consultant Physician, Royal Brompton & Harefield NHS Trust, London, United Kingdom
Ch. 30 Cough

Pr Christine Clerici

Physiologie-Explorations Fonctionnelles, Hopitaux Universitaires Paris Nord Val de Seine, INSERM U1152, UFR de Médecine Paris Diderot, Paris 7, France
Ch. 9 Alveolar Epithelium and Fluid Transport

Thomas V. Colby, MD

Geraldine C. Zeiler Professor of Cytopathology, Laboratory Medicine and Pathology, Mayo Clinic, Scottsdale, Arizona
Ch. 63 Idiopathic Interstitial Pneumonias

Harold R. Collard, MD

Associate Professor of Clinical Medicine, University of California San Francisco, Director, Interstitial Lung Disease Program, UCSF Medical Center, San Francisco, California
Ch. 67 Alveolar Hemorrhage and Rare Infiltrative Diseases

Carlyne D. Cool, MD

Clinical Professor of Pathology, Department of Pathology, University of Colorado, Denver School of Medicine, Aurora, Colorado; Division of Pathology, National Jewish Health, Denver, Colorado
Ch. 60 Pulmonary Vasculitis

Jean-François Cordier, MD

Professor of Respiratory Medicine, Claude Bernard University, Department of Respiratory Medicine, Louis Pradel University Hospital, Lyon, France
Ch. 54 Rare Primary Lung Tumors
Ch. 68 Eosinophilic Lung Diseases

Ricardo Luiz Cordioli, MD, PhD

Medical Staff, Intensive Care, Albert Einstein Hospital, Medical Staff, Intensive Care, Oswaldo Cruz Hospital, São Paulo, Brazil
Ch. 102 Noninvasive Ventilation

Tamera J. Corte, MBBS, FRACP

Associate Professor, Department of Medicine, University of Sydney Medical School, Consultant Respiratory Physician, Interstitial Lung Disease Clinic, Royal Prince Alfred Hospital, Sydney, Australia
Ch. 65 Connective Tissue Diseases

Vincent Cottin, MD, PhD

Professor of Respiratory Medicine, Université Claude Bernard Lyon 1, Reference Center for Rare Pulmonary Diseases, Hospices Civils de Lyon, Louis Pradel Hospital, Lyon, France
Ch. 68 Eosinophilic Lung Diseases

Mark S. Courey, MD

Professor of Clinical Otolaryngology, Department of Otolaryngology—Head and Neck Surgery, University of California San Francisco, Director of Laryngology, Medical Director, Voice and Swallowing Center, UCSF Medical Center, San Francisco, California
Ch. 49 Upper Airway Disorders

Robert L. Cowie, MD

Professor. Departments of Medicine and of Community Health Sciences, University of Calgary Faculty of Medicine, Respiriologist, Department of Medicine, Alberta Health Services, Calgary, Alberta, Canada
Ch. 73 Pneumoconioses

Kristina Crothers, MD

Associate Professor of Medicine, Division of Pulmonary and Critical Care Medicine, University of Washington School of Medicine, Seattle, Washington

Ch. 90 Pulmonary Complications of HIV Infection

Gerard F. Curley, MB, MSc, PhD, FCAI

Assistant Professor, Department of Anesthesia, University of Toronto Faculty of Medicine, Associate Scientist, Keenan Research Centre for Biomedical Science of St. Michael's Hospital, Staff Anesthesiologist, St. Michael's Hospital, Toronto, Ontario, Canada

Ch. 86 Hypocapnia and Hypercapnia

Charles L. Daley, MD

Professor and Head, Division of Mycobacterial and Respiratory Infections, National Jewish Health, Denver, Colorado; Professor of Medicine, Division of Pulmonary and Critical Care Medicine and Infectious Diseases, University of Colorado, Denver, Aurora, Colorado

Ch. 36 Nontuberculous Mycobacterial Infections

J. Lucian Davis, MD, MAS

Associate Professor, Division of Pulmonary and Critical Care Medicine, Department of Medicine, University of California San Francisco, San Francisco General Hospital, San Francisco, California

Ch. 16 History of Physical Examination

Teresa De Marco, MD, FACC

Professor, Clinical Medicine and Surgery, R. H. and Jane G. Logan Endowed Chair in Cardiology, Director, Advanced Heart Failure and Pulmonary Hypertension, Medical Director, Heart Transplantation, University of California San Francisco, San Francisco, California

Ch. 59 Pulmonary Hypertension due to Lung Disease

Stanley C. Deresinski, MD

Clinical Professor, Department of Medicine (Division of Infectious Diseases and Geographic Medicine), Stanford University School of Medicine, Stanford, California

Ch. 17 Microbiologic Diagnosis of Lung Infection

Christophe Deroose, MD, PhD

Associate Professor, Department of Nuclear Medicine & Molecular Imaging, Catholic University Leuven, Leuven, Belgium

Ch. 21 Positron Emission Tomography

Leland G. Dobbs, MD

Adjunct Professor of Medicine and Pediatrics, University of California San Francisco, Cardiovascular Research Institute at UCSF, San Francisco, California

Ch. 8 Alveolar Epithelium and Pulmonary Surfactant

Christophe Doods, MD, PhD

Assistant Professor, Department of Pneumology, Catholic University Leuven, Leuven, Belgium

Ch. 21 Positron Emission Tomography

Gregory P. Downey, MD

Executive Vice President, Academic Affairs, Department of Medicine, National Jewish Health, Professor, Department of Medicine and Integrated Department of Immunology, University of Colorado Denver, Aurora, Colorado

Ch. 15 Injury and Repair

Roland M. du Bois, MD, FRCP, FCCP

Emeritus Professor of Respiratory Medicine, Imperial College London, London, United Kingdom

Ch. 65 Connective Tissue Diseases

Megan M. Duloher, MD

Instructor of Medicine, Department of Internal Medicine, Division of Pulmonary and Critical Care, Mayo Clinic, Rochester, Minnesota

Ch. 71 Drug-Induced Pulmonary Disease

Richard M. Effros, MD

Clinical Professor, Department of Medicine, LA Biomed/Harbor-UCLA Medical Center, Torrance, California; Professor Emeritus, Department of Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin

Ch. 7 Acid-Base Balance

Mark D. Eisner, MD, MPH

Senior Group Medical Director, Product Development, Genentech, South San Francisco, California

Ch. 74 Indoor and Outdoor Air Pollution

Brett M. Elicker, MD

Associate Professor of Clinical Radiology, Department of Radiology and Biomedical Imaging, University of California San Francisco, San Francisco, California

Ch. 18 Thoracic Radiology: Noninvasive Diagnostic Imaging

Armin Ernst, MD, MHCM

President and CEO, Reliant Medical Group, Professor of Medicine, Tufts University School of Medicine, Boston, Massachusetts

Ch. 20 Ultrasonography

Joel D. Ernst, MD

Director, Division of Infectious Diseases and Immunology, Jeffrey Bergstein Professor of Medicine, Professor of Medicine, Pathology and Microbiology, New York University School of Medicine, NYU Langone Medical Center, New York, New York

Ch. 35 Tuberculosis

John V. Fahy, MD, MSc

Professor of Medicine, Pulmonary, Critical Care, Allergy and Sleep Medicine, Cardiovascular Research Institute, University of California San Francisco, San Francisco, California

Ch. 41 Asthma: Pathogenesis and Phenotypes

Peter F. Fedullo, MD

Professor of Medicine and Chief of Staff, Division of Pulmonary and Critical Care Medicine, University of California San Diego School of Medicine, UCSD Medical Center, San Diego, California
Ch. 57 Pulmonary Thromboembolism

David Feller-Kopman, MD, FACP

Associate Professor of Medicine, Department of Pulmonary & Critical Care Medicine, Director, Bronchoscopy & Interventional Pulmonology, Johns Hopkins Hospital, Baltimore, Maryland
Ch. 22 Diagnostic Bronchoscopy
Ch. 23 Therapeutic Bronchoscopy

Brett E. Fenster, MD, FACC, FASE

Associate Professor of Medicine, Division of Cardiology, Director, Pulmonary Hypertension Center, National Jewish Health, Denver, Colorado
Ch. 31 Chest Pain

Tasha E. Fingerlin, MS, PhD

Associate Professor, Departments of Epidemiology & Biostatistics and Informatics, University of Colorado Anschutz Medical Campus, Aurora, Colorado
Ch. 3 Genetics of Lung Disease

Andrew P. Fontenot, MD

Henry N. Claman Professor of Medicine, University of Colorado Anschutz Medical Campus, Aurora, Colorado
Ch. 13 Adaptive Immunity

Stephen K. Frankel, MD, FCCM, FCCP

Professor of Medicine, Chief Medical Officer, National Jewish Health, Denver, Colorado; Professor of Medicine, University of Colorado, Denver School of Medicine, Aurora, Colorado
Ch. 60 Pulmonary Vasculitis

Joe G. N. Garcia, MD

Senior Vice President for Health Sciences, Department of Medicine, University of Arizona, Tucson, Arizona
Ch. 6 Pulmonary Circulation and Regulation of Fluid Balance

G. F. Gebhart, PhD

Professor of Anesthesiology, Medicine, Neurobiology and Pharmacology, Director, Center for Pain Research, University of Pittsburgh, Pittsburgh, Pennsylvania
Ch. 31 Chest Pain

Daniel Lee Gilstrap, MD

Medical Instructor, Department of Medicine, Duke University Medical Center, Durham, North Carolina
Ch. 42 Asthma: Clinical Diagnosis and Management

Nicolas Girard, MD, PhD

Professor of Respiratory Medicine, Claude-Bernard University, Department of Respiratory Medicine, Louis Pradel Hospital, Hospices Civils de Lyon, Lyon, France
Ch. 54 Rare Primary Lung Tumors

Mark T. Gladwin, MD

Professor of Medicine, Division of Pulmonary, Allergy, and Critical Care Medicine, Director, Heart, Lung, Blood and Vascular Medicine Institute, University of Pittsburgh School of Medicine, Division Chief, Pulmonary, Allergy and Critical Care Medicine, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Ch. 94 Pulmonary Complications of Hematologic Diseases

Robb W. Glenny, MD

Professor, Departments of Medicine and of Physiology and Biophysics, Division of Pulmonary and Critical Care Medicine, University of Washington School of Medicine, Seattle, Washington
Ch. 26 Clinical Exercise Testing

Warren M. Gold, MD

Professor of Medicine Emeritus, Senior Staff, Cardiovascular Research Institute, University of California San Francisco, Attending Physician, Division of Pulmonary, Sleep and Critical Care, Department of Medicine, Moffitt-Long Hospitals, San Francisco, California
Ch. 25 Pulmonary Function Testing

Michael B. Gotway, MD

Professor of Radiology, Mayo Clinic, Scottsdale, Arizona; Clinical Associate Professor, Diagnostic Radiology/Biomedical Imaging and Pulmonary/Critical Care Medicine, Department of Radiology and Biomedical Imaging, University of California San Francisco, San Francisco, California; Clinical Professor, University of Arizona College of Medicine, Phoenix, Arizona; Adjunct Professor, Department of Biomedical Informatics, Arizona State University, Tempe, Arizona
Ch. 18 Thoracic Radiology: Noninvasive Diagnostic Imaging

Giacomo Grasselli, MD

Department of Health Sciences, School of Medicine, University of Milan-Bicocca, Emergency Department, Ospedale San Gerardo, Monza, Italy
Ch. 103 Extracorporeal Support of Gas Exchange

James M. Greenberg, MD

Professor of Pediatrics, Director, Division of Neonatology, University of Cincinnati College of Medicine, Co-Director, Perinatal Institute, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio
Ch. 2 Lung Growth and Development

David E. Griffith, MD

William A. and Elizabeth B. Moncrief Distinguished Professorship in Comprehensive Heart and Lung Disease, Director of the Pulmonary and Critical Care Division, University of Texas Health Science Center, Professor of Medicine, University of Texas Health Science Center, Tyler, Texas; Medical Director, Texas Center for Infectious Disease, Assistant Medical Director, Heartland National Tuberculosis Center, San Antonio, Texas
Ch. 36 Nontuberculous Mycobacterial Infections

James F. Gruden, MD

Associate Professor of Radiology, Mayo Clinic, Scottsdale, Arizona

Ch. 18 Thoracic Radiology: Noninvasive Diagnostic Imaging

MeiLan King Han, MD, MS

Associate Professor of Medicine, Division of Pulmonary and Critical Care Medicine, University of Michigan School of Medicine, Ann Arbor, Michigan

Ch. 44 COPD: Clinical Diagnosis and Management

William Henderson, MD, FRCPC

Assistant Professor, Division of Critical Care Medicine, Vancouver General Hospital, Vancouver, British Columbia, Canada

Ch. 5 Respiratory System Mechanics and Energetics

Nicholas S. Hill, MD

Chief, Division of Pulmonary, Critical Care and Sleep Medicine, Tufts Medical Center, Professor of Medicine, Tufts University School of Medicine, Boston, Massachusetts

Ch. 99 Acute Ventilatory Failure

Wynton Hoover, MD

Associate Professor of Pediatrics, Division of Pulmonary and Sleep Medicine, University of Alabama at Birmingham, Birmingham, Alabama

Ch. 47 Cystic Fibrosis

Philip C. Hopewell, MD

Professor of Medicine, Director, Curry International TB Center, University of California San Francisco, San Francisco General Hospital, San Francisco, California

Ch. 35 Tuberculosis

Jennifer L. Horan-Saullo, MD, PharmD

Instructor, Department of Medicine, Division of Infectious Diseases, Duke University, Durham, North Carolina

Ch. 38 Opportunistic Mycoses

Richard L. Horner, PhD

Professor, Departments of Medicine and Physiology, University of Toronto, Canada Research Chair in Sleep and Respiratory Neurobiology, Toronto, Ontario, Canada

Ch. 85 Control of Breathing and Upper Airways During Sleep

Laurence Huang, MD, MAS

Professor of Medicine, University of California San Francisco, Chief, HIV/AIDS Chest Clinic, San Francisco General Hospital, San Francisco, California

Ch. 90 Pulmonary Complications of HIV Infection

Gérard Huchon, MD

Professor of Medicine (Respiratory Diseases), Service de Pneumologie, Université Paris 5 René Descartes, Paris, France

Ch. 93 Pulmonary Complications of Abdominal Diseases

Yoshikazu Inoue, MD, PhD

Director, Department of Diffuse Lung Diseases and Respiratory Failure, National Hospital Organization Kinki-Chuo Chest Medical Center, Sakai, Osaka, Japan

Ch. 69 Lymphangioleiomyomatosis

Michael D. Iseman, MD, FACP, FCCP

Professor of Medicine, Divisions of Pulmonary Medicine and Infectious Diseases, University of Colorado Anschutz Medical Campus, Staff Physician, Division of Mycobacterial and Respiratory Infections, National Jewish Health, Denver, Colorado

Ch. 48 Bronchiectasis

James E. Jackson, MBBS, MRCP, FRCR

Consultant Radiologist, Department of Imaging, Hammersmith Hospital, London, United Kingdom

Ch. 61 Pulmonary Vascular Abnormalities

Claudia V. Jakubzick, PhD

Assistant Professor, Department of Pediatrics, Integrated Department of Immunology, National Jewish Health, Denver, Colorado

Ch. 12 Innate Immunity

Julius P. Janssen, MD, PhD

Department of Pulmonary Diseases, Canisius Wilhelmina Hospital, Nijmegen, The Netherlands

Ch. 24 Thoracoscopy

James R. Jett, MD, FCCP

Professor of Medicine (Oncology), Director, Clinical and Translational Research Section, National Jewish Health, Denver, Colorado

Ch. 53 Clinical Aspects of Lung Cancer

Kirk Jones, MD

Professor of Medicine, Department of Pathology, University of California San Francisco, San Francisco, California

Ch. 50 Bronchiolitis and Other Intrathoracic Airway Disorders

Marc A. Judson, MD

Chief, Division of Pulmonary and Critical Care Medicine, Albany Medical Center, Albany, New York

Ch. 66 Sarcoidosis

Midori Kato-Maeda, MD, MS

Associate Professor of Medicine, University of California San Francisco, San Francisco General Hospital, San Francisco, California

Ch. 35 Tuberculosis

Brian P. Kavanagh, MB, FRCPC

Professor, Departments of Anesthesia, Physiology & Medicine, University of Toronto Faculty of Medicine, Dr. Geoffrey Barker Chair of Critical Care Medicine, Hospital for Sick Children, Toronto, Ontario, Canada

Ch. 86 Hypocapnia and Hypercapnia

Shaf Keshavjee, MD, MSc, FRCSC, FACS

Surgeon-in-Chief, Sprott Department of Surgery, Toronto General Hospital, Director, Toronto Lung Transplant Program, University Health Network, Director, Latner Thoracic Research Laboratories, University Health Network, Professor, Division of Thoracic Surgery & Institute of Biomaterials and Biomedical Engineering, University of Toronto, University Health Network, Toronto, Ontario, Canada

Ch. 106 Lung Transplantation

Kami Kim, MD

Professor, Departments of Medicine, Microbiology & Immunology, and Pathology, Albert Einstein College of Medicine, Bronx, New York

Ch. 39 Parasitic Infections

R. John Kimoff, MD, FRCP(C), ABIM (Sleep)

Director, Sleep Laboratory, Respiratory Division, McGill University Health Centre, Montreal, Quebec, Canada

Ch. 88 Obstructive Sleep Apnea

Talmadge E. King, Jr., MD

Julius R. Krevans Distinguished Professorship in Internal Medicine, Chair, Department of Medicine, University of California San Francisco, San Francisco, California

Ch. 63 Idiopathic Interstitial Pneumonias

Ch. 67 Alveolar Hemorrhage and Rare Infiltrative Diseases

Jeffrey S. Klein, MD, FACR

A. Bradley Soule and John P. Tampas Green and Gold Professor of Radiology, University of Vermont College of Medicine, Editor, *RadioGraphics*, Radiological Society of North America, Burlington, Vermont

Ch. 19 Thoracic Radiology: Invasive Diagnostic Imaging and Image-Guided Interventions

Laura L. Koth, MD

Associate Professor of Clinical Medicine, Director, Adult Pulmonary Function Laboratory, Cardiovascular Research Institute, Attending Physician, Division of Pulmonary, Sleep, and Critical Care, Department of Medicine, Moffitt-Long Hospitals, San Francisco, California

Ch. 25 Pulmonary Function Testing

Robert M. Kotloff, MD

Chairman, Department of Pulmonary Medicine, Respiratory Institute, Cleveland Clinic, Cleveland, Ohio

Ch. 106 Lung Transplantation

Monica Kraft, MD

Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Duke University Medical Center, Durham, North Carolina

Ch. 42 Asthma: Clinical Diagnosis and Management

Elif Küpeli, MD, FCCP

Associate Professor of Medicine, Baskent University School of Medicine, Pulmonary Department, Ankara, Turkey

Ch. 22 Diagnostic Bronchoscopy

John G. Laffey, MD, MA, FCAI

Anesthesiologist-in-Chief, Department of Anesthesia, Keenan Research Centre for Biomedical Science of St. Michael's Hospital, Professor, Departments of Anesthesia and Physiology, University of Toronto Faculty of Medicine, Toronto, Ontario, Canada

Ch. 86 Hypocapnia and Hypercapnia

Stephen E. Lapinsky, MBBCh, MSc, FRCPC

Professor, Department of Medicine, University of Toronto, Site Director, Intensive Care Unit, Mount Sinai Hospital, Toronto, Ontario, Canada

Ch. 96 The Lungs in Obstetric and Gynecologic Diseases

Stephen C. Lazarus, MD

Professor of Medicine, Division of Pulmonary, Critical Care, Allergy & Sleep Medicine, Director, Training Program in Pulmonary & Critical Care Medicine, Associate Director, Adult Pulmonary Laboratory, Senior Investigator, Cardiovascular Research Institute, University of California San Francisco, San Francisco, California

Ch. 44 COPD: Clinical Diagnosis and Management

Ch. 50 Bronchiolitis and Other Intrathoracic Airway Disorders

Frances Eun-Hyung Lee, MD

Assistant Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Director, Emory Asthma, Allergy, Immunology Program, Emory University School of Medicine, Atlanta, Georgia

Ch. 32 Viral Infections

Jarone Lee, MD, MPH

Instructor in Surgery, Harvard Medical School, Division of Trauma, Emergency Surgery, Surgical Critical Care, Massachusetts General Hospital, Boston, Massachusetts

Ch. 76 Trauma and Blast Injuries

Y. C. Gary Lee, MBChB, PhD, FRACP, FCCP, FRCP

Winthrop Professor of Respiratory Medicine, Centre for Asthma, Allergy, and Respiratory Research, School of Medicine and Pharmacology, University of Western Australia, Consultant, Department of Respiratory Medicine, Director of Pleural Services, Sir Charles Gairdner Hospital, Perth, Australia

Ch. 81 Pneumothorax, Chylothorax, Hemothorax, and Fibrothorax

Warren L. Lee, MD, PhD, FRCP(C)

Assistant Professor of Medicine, Division of Respiriology and the Interdepartmental Division of Critical Care Medicine, University of Toronto, Attending Physician, Medical-Surgical Intensive Care Unit, St. Michael's Hospital, Staff Scientist, Keenan Research Centre, Li Ka Shing Knowledge Institute, St. Michael's Hospital, Toronto, Ontario, Canada

Ch. 100 Acute Hypoxemic Respiratory Failure and ARDS

Teofilo L. Lee-Chiong, Jr., MD

Professor of Medicine, National Jewish Health, University of Colorado, Denver, Colorado; Chief Medical Liaison, Philips Respironics, Monroeville, Pennsylvania
Ch. 31 Chest Pain

Catherine Lemièrre, MD, MSc

Professor of Medicine, Université de Montréal Faculty of Medicine, Chest Physician, Department of Medicine, Hôpital du Sacré-Coeur de Montréal, Montréal, Québec, Canada
Ch. 72 Asthma in the Workplace

Richard W. Light, MD

Professor of Medicine, Division of Allergy, Pulmonary, and Critical Care Medicine, Vanderbilt University School of Medicine, Nashville, Tennessee
Ch. 79 Pleural Effusion
Ch. 80 Pleural Infections
Ch. 81 Pneumothorax, Chylothorax, Hemothorax, and Fibrothorax

Andrew H. Limper, MD

Annenberg Professor of Pulmonary Research, Associate Chair for Research, Department of Internal Medicine, Director, Thoracic Diseases Research Unit, Mayo Clinic College of Medicine, Rochester, Minnesota
Ch. 71 Drug-Induced Pulmonary Disease

Robert Loddenkemper, MD

Professor of Medicine, Charité University Medicine, Former Director and Chief of Department of Pneumology, HELIOS-Klinikum Emil von Behring, Berlin, Germany
Ch. 24 Thoracoscopy

Njira Lugogo, MD

Assistant Professor of Medicine, Duke Asthma, Allergy and Airway Center, Duke University Medical Center, Durham, North Carolina
Ch. 42 Asthma: Clinical Diagnosis and Management

Maurizio Luisetti, MD

Professor of Respiratory Disease, Department of Molecular Medicine, University of Pavia, Head, Pneumology Section, San Matteo Hospital Foundation, Pavia, Italy
Ch. 70 Pulmonary Alveolar Proteinosis Syndrome

Andrew M. Luks, MD

Associate Professor of Medicine, Division of Pulmonary and Critical Care Medicine, University of Washington School of Medicine, Seattle, Washington
Ch. 26 Clinical Exercise Testing
Ch. 77 High Altitude

Charles-Edouard Luyt, MD, PhD

Service de Réanimation Médicale, Institut de Cardiologie, Groupe Hospitalier Pitié-Salpêtrière, Paris, France
Ch. 34 Ventilator-Associated Pneumonia

Roberto F. Machado, MD

Associate Professor of Medicine, Division of Pulmonary, Critical Care Medicine, Sleep and Allergy, Department of Medicine, University of Illinois, Chicago, Chicago, Illinois
Ch. 94 Pulmonary Complications of Hematologic Diseases

Neil R. MacIntyre, MD

Professor of Medicine, Department of Medicine, Duke University, Durham, North Carolina
Ch. 101 Mechanical Ventilation

William MacNee, MB, ChB, MD, FRCP(G), FRCP(E)

Professor of Respiratory and Environmental Medicine, Honorary Consultant Physician, University of Edinburgh, Edinburgh, United Kingdom
Ch. 43 COPD: Pathogenesis and Natural History

David K. Madtes, MD

Member, Clinical Research Division, Fred Hutchinson Cancer Research Center, Associate Professor Medicine, University of Washington, Seattle, Washington
Ch. 91 Pulmonary Complications of Stem Cell and Solid Organ Transplantation

Lisa A. Maier, MD, MSPH, FCCP

Chief, Division of Environmental and Occupational Health Sciences, National Jewish Health, Professor of Medicine, Division of Pulmonary Sciences and Critical Care Medicine, Department of Environmental/Occupational Health, Colorado School of Public Health, University of Colorado, Denver, Denver, Colorado
Ch. 28 Evaluation of Respiratory Impairment and Disability

Fabien Maldonado, MD

Assistant Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Mayo Clinic College of Medicine, Rochester, Minnesota
Ch. 71 Drug-Induced Pulmonary Disease

Atul Malhotra, MD

Kenneth M. Moser Professor of Medicine, Chief of Pulmonary and Critical Care Medicine, Director of Sleep Medicine, University of California San Diego, La Jolla, California
Ch. 85 Control of Breathing and Upper Airways During Sleep
Ch. 87 Consequences of Sleep Disruption

Thomas R. Martin, MD

Global Head, Respiratory Therapeutic Area, Development, Novartis Pharmaceuticals, East Hanover, New Jersey
Ch. 12 Innate Immunity

Nick A. Maskell, DM, FRCP

Reader in Respiratory Medicine, School of Clinical Sciences, University of Bristol, Bristol, United Kingdom
Ch. 80 Pleural Infections

Robert J. Mason, MD

Cetalia & Marcel Weiss Chair in Pulmonary Medicine,
Department of Medicine, National Jewish Health,
Denver, Colorado; Professor of Medicine, University of
Colorado Denver Health Sciences Center, Aurora,
Colorado
Ch. 8 Alveolar Epithelium and Pulmonary Surfactant

Pierre P. Massion, MD

Professor of Medicine and Cancer Biology, Department of
Medicine, Vanderbilt University School of Medicine,
Director of the Thoracic Program, Vanderbilt-Ingram
Cancer Center, Nashville, Tennessee
Ch. 51 Biology of Lung Cancer

Michael A. Matthay, MD

Professor, Departments of Medicine and Anesthesia,
University of California San Francisco, San Francisco,
California
Ch. 9 Alveolar Epithelium and Fluid Transport
Ch. 62 Pulmonary Edema

Richard A. Matthay, MD

Professor Emeritus and Senior Research Scientist in
Medicine, Section of Pulmonary, Critical Care and Sleep
Medicine, Yale University School of Medicine, New
Haven, Connecticut
Ch. 31 Chest Pain

Annyce S. Mayer, MD, MSPH

Associate Professor of Medicine, Division of
Environmental and Occupational Health Sciences,
National Jewish Health, Department of Environmental/
Occupational Health, Colorado School of Public Health,
University of Colorado, Denver, Colorado
*Ch. 28 Evaluation of Respiratory Impairment and
Disability*

Stuart B. Mazzone, PhD

Senior Research Fellow, Laboratory of Respiratory
Neuroscience and Mucosal Immunity, The University of
Queensland School of Biomedical Sciences, St. Lucia,
Queensland, Australia
Ch. 30 Cough

F. Dennis McCool, MD

Professor of Medicine, Division of Pulmonary and Critical
Care Medicine, Alpert Medical School of Brown
University, Providence, Rhode Island; Memorial
Hospital of Rhode Island, Pawtucket, Rhode Island
*Ch. 97 The Respiratory System and Neuromuscular
Diseases*
*Ch. 98 The Respiratory System and Chest Wall
Diseases*

Francis Xavier McCormack, MD

Taylor Professor and Director, Division of Pulmonary,
Critical Care and Sleep Medicine, University of
Cincinnati, Cincinnati, Ohio
Ch. 69 Lymphangiomyomatosis

Atul C. Mehta, MBBS, FACP, FCCP

Department of Pulmonary Medicine, Respiratory
Institute, Cleveland Clinic, Professor of Medicine, Lerner
College of Medicine, Cleveland, Ohio
Ch. 22 Diagnostic Bronchoscopy
Ch. 23 Therapeutic Bronchoscopy

Rosario Menéndez, MD, PhD

Pulmonologist, Directora del Área de Enfermedades
Respiratorias, Hospital Universitario La Fe, Valencia,
Spain
Ch. 33 Bacterial Pneumonia and Lung Abscess

Adam S. Morgenthau, MD

Assistant Professor of Medicine, Division of Pulmonary,
Critical Care and Sleep Medicine, Icahn School of
Medicine at Mount Sinai, New York, New York
Ch. 66 Sarcoidosis

Alison Morris, MD, MS

Associate Professor of Medicine and Immunology, Division
of Pulmonary, Allergy, and Critical Care Medicine,
University of Pittsburgh School of Medicine, Pittsburgh,
Pennsylvania
Ch. 90 Pulmonary Complications of HIV Infection

Timothy A. Morris, MD, FCCP

Professor of Medicine and Clinical Service Chief, Division
of Pulmonary and Critical Care Medicine, University of
California, San Diego School of Medicine, UCSD Medical
Center, San Diego, California
Ch. 57 Pulmonary Thromboembolism

Aaron R. Muncey, MD

Clinical Fellow, Department of Anesthesiology, Brigham
and Women's Hospital, Boston, Massachusetts
Ch. 87 Consequences of Sleep Disruption

John F. Murray, MD, FRCP, DSc (Hon)

Professor Emeritus, Department of Medicine, University of
California San Francisco, San Francisco General
Hospital, San Francisco, California
Ch. 16 History of Physical Examination
Ch. 62 Pulmonary Edema

Jeffrey L. Myers, MD

A. James French Professor of Pathology, Director,
Divisions of Anatomic Pathology and MLabs, University
of Michigan School of Medicine, Ann Arbor, Michigan
Ch. 56 Benign Lung Tumors

Jay A. Nadel, MD, DSc (Hon), DLaw (Hon)

Professor of Medicine, Physiology, and Radiology, Division
of Pulmonary and Critical Care Medicine,
Cardiovascular Research Institute, University of
California San Francisco, San Francisco, California
Ch. 10 Airway Epithelium and Mucous Secretion

Catherine Nelson-Piercy, MBBA, MA, FRCP, FRCOG

Professor of Obstetric Medicine, Women's Health Academic Centre, King's Health Partners, Consultant Obstetric Physician, Women's Health, Guy's & St. Thomas' Foundation Trust, Consultant Obstetric Physician, Queen Charlotte's and Chelsea Hospital, Imperial College Healthcare Trust, London, Great Britain

Ch. 96 The Lungs in Obstetric and Gynecologic Diseases

Tom S. Neuman, MD

Professor Emeritus, Department of Emergency Medicine, University of California, San Diego, San Diego, California

Ch. 78 Diving Medicine

Joshua D. Nosanchuk, MD

Professor of Medicine and Microbiology & Immunology, Assistant Dean of Students, Albert Einstein College of Medicine, Bronx, New York

Ch. 37 Endemic Mycoses

Thomas G. O'Riordan, MD

Clinical Associate Professor of Medicine, Division of Pulmonary & Critical Care Medicine, University of Washington School of Medicine, Senior Director of Clinical Research, Gilead Sciences Inc., Seattle, Washington

Ch. 11 Aerosol Deposition and Clearance

Victor Enrique Ortega, MD

Assistant Professor of Medicine, Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, North Carolina

Ch. 45 Genetics in Asthma and COPD

Prasad M. Panse, MD

Assistant Professor of Radiology, Mayo Clinic, Scottsdale, Arizona

Ch. 18 Thoracic Radiology: Noninvasive Diagnostic Imaging

William Pao, MD, PhD

Cornelius Abernathy Craig Professor of Medical & Surgical Oncology, Medicine, Vanderbilt University School of Medicine, Director, Personalized Cancer Medicine, Vanderbilt-Ingram Cancer Center, Nashville, Tennessee

Ch. 51 Biology of Lung Cancer

Peter A. Paré, MD

Professor, Departments of Respiratory Medicine and Pathology, University of British Columbia, James Hogg Research Centre, Institute for Heart + Lung Health, St. Paul's Hospital, Vancouver, British Columbia, Canada

Ch. 5 Respiratory System Mechanics and Energetics

David R. Park, MD

Professor, Division of Pulmonary and Critical Care Medicine, Adjunct Professor, Department of Global Health, University of Washington School of Medicine, Seattle, Washington

Ch. 83 Mediastinal Tumors and Cysts

Ch. 84 Pneumomediastinum and Mediastinitis

Nicholas J. Pastis, MD, FCCP

Assistant Professor of Medicine, Division of Pulmonary and Critical Care, Medical University of South Carolina, Charleston, South Carolina

Ch. 53 Clinical Aspects of Lung Cancer

Nicolò Patroniti, MD

Associate Professor of Anesthesiology, Department of Health Sciences, School of Medicine, University of Milan-Bicocca, Emergency Department, Ospedale San Gerardo, Monza, Italy

Ch. 103 Extracorporeal Support of Gas Exchange

Karen C. Patterson, MD

Clinical Instructor, Division of Pulmonary, Allergy and Critical Care, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania

Ch. 64 Hypersensitivity Pneumonitis

Antonio Pesenti, MD

Professor of Anesthesiology, Department of Health Sciences, University of Milan-Bicocca, Director, Emergency Department, Ospedale San Gerardo, Monza, Italy

Ch. 103 Extracorporeal Support of Gas Exchange

Allan Pickens, MD

Assistant Professor of Surgery, Emory University School of Medicine, Director of Minimally Invasive Surgery and Thoracic Oncology, Section of Cardiothoracic Surgery, Emory University Hospital, Atlanta, Georgia

Ch. 55 Metastatic Malignant Tumors

Benjamin A. Pinsky, MD, PhD

Assistant Professor, Departments of Pathology and Medicine (Division of Infectious Diseases and Geographic Medicine), Stanford University School of Medicine, Director, Clinical Virology Laboratory, Stanford University Medical Center, Stanford, California

Ch. 17 Microbiologic Diagnosis of Lung Infection

Steven D. Pletcher, MD

Associate Professor of Clinical Otolaryngology, Department of Otolaryngology—Head and Neck Surgery, University of California San Francisco, San Francisco, California

Ch. 49 Upper Airway Disorders

Frank L. Powell, PhD

Professor of Medicine, University of California, San Diego School of Medicine, La Jolla, California

Ch. 4 Ventilation, Blood Flow, and Gas Exchange

Loretta G. Que, MD

Associate Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Duke University School of Medicine, Durham, North Carolina

Ch. 42 Asthma: Clinical Diagnosis and Management

Elizabeth F. Redente, PhD

Assistant Professor, Department of Pediatrics, Division of Cell Biology, National Jewish Health, Denver, Colorado

Ch. 12 Innate Immunity

David W. H. Riches, PhD

Professor, Division of Pulmonary Sciences and Critical Care Medicine, Departments of Medicine and Immunology, University of Colorado Denver School of Medicine, Aurora, Colorado; Professor and Division Head, Program in Cell Biology, National Jewish Health, Denver, Colorado

Ch. 12 Innate Immunity

Bruce W. S. Robinson, MBBS, MD, FRACP, FRCP, DTM&H, FCCP

Consultant Respiratory Physician, UWA School Of Medicine, Sir Charles Gairdner Hospital, Perth, WA, Australia

Ch. 82 Pleural Tumors

Roberto Rodriguez-Roisin, MD, PhD, FRCP (Edinburgh)

Professor, Department of Medicine, Universitat de Barcelona, School of Medicine, Senior Consultant Physician, Thorax Institute (Respiratory Medicine), Hospital Clinic, Barcelona, Spain

Ch. 93 Pulmonary Complications of Abdominal Diseases

Cecile S. Rose, MD, MPH

Director, Occupational Medicine Program, Department of Medicine, National Jewish Health, Denver, Colorado; Professor of Medicine, Division of Pulmonary Sciences and Critical Care, University of Colorado, Denver, Aurora, Colorado

Ch. 64 Hypersensitivity Pneumonitis

John M. Routes, MD

Professor of Pediatrics, Medicine, Microbiology and Molecular Genetics, Medical College of Wisconsin, Chief, Section of Allergy and Clinical Immunology, Children's Hospital of Wisconsin, Milwaukee, Wisconsin

Ch. 92 Pulmonary Complications of Primary Immunodeficiencies

Steven M. Rowe, MD, MSPH

Associate Professor of Medicine, Division of Pulmonary, Allergy, and Critical Care, University of Alabama at Birmingham, Birmingham, Alabama

Ch. 47 Cystic Fibrosis

Clodagh M. Ryan, MB, BCh, BAO, MD, FRCPC

Assistant Professor of Medicine, University of Toronto, University Health Network, Toronto General Hospital and Toronto Rehabilitation Institute Toronto, Ontario, Canada

Ch. 89 Central Sleep Apnea

Jay H. Ryu, MD

Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Mayo Clinic College of Medicine, Rochester, Minnesota

Ch. 63 Idiopathic Interstitial Pneumonias

Care Medicine, University of Connecticut School of
Medicine, Farmington, Connecticut; Associate Chief,
Pulmonary and Critical Care, St. Francis Hospital and
Medical Center, Hartford, Connecticut
Ch. 105 Pulmonary Rehabilitation

Preface to the Sixth Edition

In this *Preface to the Sixth Edition of Murray & Nadel's Textbook of Respiratory Medicine*, the Editors are pleased to highlight the new features that enhance the readability and educational value of the book. Whereas advances in both the Fourth and Fifth Editions increasingly incorporated online resources, with the Sixth Edition, the textbook has become truly digital.

The Expert Consult eBook version of the Sixth Edition now provides easier navigation, more thorough and precise searching and retrieval capabilities, and extensive resource material. Via the eBook, readers will have access to nearly 200 videos and audio files and more than 600 new eFigures; there are also extensive cross references to other figures and videos throughout the book. Whereas Key Readings are listed for each chapter in both hardcover and electronic versions, the eBook contains the entire, extensive bibliography where the reader can access each reference by clicking the in-text citation, thereby opening the abstract and accessing direct links to PubMed. The eBook contains new and revised multiple choice questions from each chapter as rich sources of educational challenge and, using the eBook, readers will be able to take notes and highlight important content for later reference. Importantly, the Expert Consult eBook will feature updates, making it a living textbook.

New chapters have been created, former chapters divided, and still others consolidated; in all, the number of chapters has increased from 95 in the Fifth Edition to 106 in the Sixth, as a reflection of the growth in knowledge of scientific and clinical aspects of respiratory health and disease. For example, the chapters on asthma and COPD have both been split: each of these major pulmonary diseases now has one chapter encompassing its molecular phenotypes and pathogenesis and another chapter outlining diagnosis and management. In addition, a chapter on the genetics of asthma and COPD has been added. The section on sleep has been expanded from one to four chapters and sections on pleural disease and fungal disease have also been expanded. New chapters have been added on positron emission tomography, therapeutic bronchoscopy, interventional radiology, bronchiolitis, pulmonary hypertension due to lung disease, non-invasive ventilation, and extra-corporeal membrane oxygenation.

Two new positions have been created: an Editor-in-Chief, who has orchestrated this complex project, and an Editor of Thoracic Imaging, who has edited all clinical images and added hundreds more to the publication. Of the total of 227 authors, 44% are first-time authors to Murray & Nadel and more than 25% hold academic positions outside the United States.

As the partnership between the scientific and clinical applications of respiration has grown and evolved since 1988—when the *Textbook of Respiratory Medicine* was initially published—two guiding axioms have reinforced every edition: first, our staunch belief in the benefit of integrating basic science with the practice of respiratory medicine and, second, the value of having an extensive and inclusive bibliography of classic works and current relevant articles.

Technical advances in publishing have led to extraordinary improvements in how information is gathered, packaged, and displayed for optimum educational benefit. We want to congratulate our publisher, Elsevier, for ensuring that these opportunities were fully realized; moreover, we wish to compliment the entire, talented publishing staff that contributed to this Sixth Edition. Particular thanks go to Jennifer Shreiner, Senior Content Development Editor, who shepherded the project from beginning to end; to Helene Caprari, Content Strategist, for guiding the book through its various stages of production; and to Mary Pohlman, Senior Project Manager, for her proofing and copyediting prowess. Finally, we acclaim the superb work of all the authors and various contributors for bringing this textbook to life, in both hard copy and in its newest digital form.

Preface to the First Edition

The rapid growth of knowledge of basic scientific principles and their application to respiratory medicine has resulted in a proliferation of monographs and texts dealing with selected aspects of pulmonary science and clinical medicine, but no single work has provided a comprehensive description of all that is currently known. The *Textbook of Respiratory Medicine* is an attempt to provide a well-balanced, authoritative, and fully documented book that integrates scientific principles with the practice of respiratory medicine. The text is sufficiently detailed and referenced to serve as the definitive source for interested students, house officers, and practitioners, both pulmonary specialists and generalists. It is written by leading experts, to guarantee that the material is authoritative and contemporary.

To deal with such an enormous amount of material, we have divided the book into three major sections. This organization should help guide interested readers from the intricacies of basic science to their application at the bedside. We begin in Part I with Scientific Principles of Respiratory Medicine. As implied, this is where the reader will find detailed information about the anatomy and development of the respiratory tract, respiratory physiology, pharmacology and pathology, and defense mechanisms and immunology. A strong foundation in these basic sciences will make possible a rational and scientific approach to the more specialized clinical material included in the subsequent sections. Part II, Manifestations and Diagnosis of Respiratory Disease, contains four chapters on the cardinal signs and symptoms of respiratory disorders and ten chapters on diagnostic evaluation, ranging from the history and physical examination to the newest and most sophisticated imaging, applied physiologic, and invasive techniques. Discrete clinical disorders are included in Part III, Clinical Respiratory Medicine. There are sections on Infectious Diseases, Obstructive Diseases, Neoplasms, Disorders of the Pulmonary Circulation, Infiltrative and Interstitial Diseases, Environmental and Occupational Disorders, Disorders of the Pleura, Disorders of the Mediastinum, Disorders in the Control of Breathing, Respiratory Manifestations of Extrapulmonary Disorders, and Respiratory Failure. All but one of the sections dealing with a generic clinical problem begin with a chapter entitled "General Principles and Diag-

nostic Approach." New challenges to adult respiratory medicine have sprung up, and these are reflected in chapters on subjects such as cystic fibrosis (previously a disease only of childhood!), environmental and occupational diseases, disorders of breathing, and respiratory problems associated with unusual atmospheres (high altitude, diving). The book ends with a novel and important section on Prevention and Control.

Putting together a *Textbook* of this scope and magnitude is no easy task and involves making certain decisions that all readers may not agree with. For example, while trying to keep the length of the book as manageable as possible, we decided to permit some overlap of content. Thus readers will find bronchodilators discussed in the chapter on airway pharmacology and again in the pertinent chapters on obstructive airway diseases. We have also welcomed differences of opinion among authors, provided the issues were clearly stated and the reasons for the author's position documented.

Our struggles were not as arduous as they might have been because we have had considerable help from many sources. First of all was the help from the 95 authors, who worked long and hard on their various contributions. The two editors worked in San Francisco, where they had the benefit of expert secretarial support from Ms. Dorothy Ladd and Mrs. Beth Cost. Special acknowledgment goes to Ms. Aja Lipavsky who, as editorial assistant, handled correspondence, proofing, permissions, and innumerable other details, and prepared the index. At W.B. Saunders in Philadelphia, the book was the brainchild of then-president John Hanley and was published with the guidance of J. Dereck Jeffers, William Lamsback, and the new president Lewis Reines. Production was supervised by Evelyn Weiman.

The long gestation of this book is over, parturition is near, and it will soon begin a life of its own. Like all expectant parents, we are concerned about how our offspring will make its way in the real world. We hope people will like it and find it useful.

THE PLEURAL SPACE AND PLEURAS
COMPARISON OF THE LUNG OF MICE
AND HUMANS

INTRODUCTION

The lung has two essential, interdependent functions. One function is ventilation-perfusion matching to deliver oxygen to the body and to remove carbon dioxide that is produced by the body (Fig. 1-1). The second function is host defense against the onslaught of airborne pathogens, chemicals, and particulates. These essential functions are emphasized through the gross, subgross, histologic, and ultrastructural determinants of respiratory gas exchange in the normal human lung. Secondary functions of the lung also are important, such as surfactant synthesis, secretion, and recycling; mucociliary clearance; neuroendocrine signaling; and synthesis and secretion of a myriad of molecules by its epithelial and endothelial cells. The diversity of secondary functions emphasizes the importance of the lung in homeostasis. The chapter finishes with comparison of the lung of mice and humans, an important subject given the widespread use of murine models in lung research. Videos 1-1 to 1-5 provide views of lung movements related to changes in tidal volume, airway pressures, and respiratory rate.

GROSS AND SUBGROSS ORGANIZATION

The position of the lungs in the chest and in relationship to the heart is shown in Fig. 1-2. Figure 1-2A shows a

midfrontal section through the thorax of a frozen human cadaver. Figure 1-2B shows a posterior-anterior chest radiograph of a normal human at *functional residual capacity* (FRC). The two illustrations represent the extremes of the approaches to lung anatomy. The cadaver lung (see Fig. 1-2A) shows the gross anatomic arrangements and relationships. The main distortion is that the lungs are at low volume. The vertical height of the lungs is only approximately 18 cm, which is well below that at FRC (see Fig. 1-2B). The diaphragm is quite elevated in Figure 1-2A, and is approximately 5 cm higher than its end-expiratory position in life. Another distortion is the abnormally wide pleural space; however, this fixation shrinkage artifact serves as a useful reminder that the lung is not normally attached to the chest wall. In life the separation between the parietal and visceral pleuras is only several micrometers.^{1,2} The chest radiograph (see Fig. 1-2B) shows that the vertical height of the lung at FRC is approximately 24 cm, with the level of the bifurcation of the pulmonary artery approximately halfway up the lungs. The diaphragm is lower and flatter than in the cadaver.

In life the human lungs weigh 900 to 1000 g, of which nearly 40% to 50% is blood.^{3,4} At end-expiration, the gas volume is approximately 2.5 L whereas, at maximal inspiration, it may be 6 L. Thus overall lung density varies from 0.30 g/mL at FRC to 0.14 g/mL at total lung capacity. But the density of the lung is not distributed uniformly, being approximately 1 g/mL near the hilum and 0.1 g/mL peripherally. If one likens each lung to a half cylinder, more than

Figure 1-1 Frozen block of lung tissue. Air is brought into the lung via the bronchus (Br) outside of which is a plate of cartilage (C). Pulmonary arterial (PA) blood is dark purple because it is poorly oxygenated. Gas exchange across the lung's parenchyma (P) results in oxygenated pulmonary venous (PV) blood, which is crimson. Also present in the peribronchovascular connective tissue are bronchial arteries (arrows) and lymphatics (L). (Frozen sheep lung, unstained.)

50% of all the lung's alveoli are located in the outer 30% of the lung radius (hilum to chest wall). This is why the peripheral portion of the lung appears relatively empty in the chest radiograph (see Fig. 1-2). Variability in density also exists from top to bottom. In Figure 1-2 the blood vessels are more distended in the lower lung fields. The increasing distention of vessels from apex to base also illustrates the increase in vascular distending pressures at the rate of 1 cm H₂O/cm height down the lung.

The disposition of the various tissues that constitute the lung is summarized in Table 1-1. An amazing point is how little tissue is involved in the architecture of the alveolar walls.^{5,6} But this is as it should be because the major physical problem of gas exchange is the slowness of oxygen diffusion through water.^{7,8} Thus the alveolar walls must be extremely thin. In fact, the thickness of the red blood cell forms a substantial portion of the air-blood diffusion pathway. Advantage was taken of this fact to separate the carbon monoxide diffusing capacity measurement into two components: the capillary blood volume and the membrane diffusing capacity.⁹ (For a discussion of diffusing capacity, see Chapters 4 and 25.)

The lung has two well-defined interstitial connective tissue compartments arranged in series, as described by Hayek¹⁰ (Fig. 1-3). These are the parenchymal (alveolar wall) interstitium and the loose-binding (extra-alveolar) connective tissue (peribronchovascular sheaths, interlobular septa, and visceral pleura). The connective tissue fibrils (collagen, elastin, and reticulin) form a three-dimensional basket-like structure around the alveoli and airways (Fig. 1-4).¹¹ This basket-like arrangement allows the lung to expand in all directions without developing excessive tissue recoil. Because the connective tissue fibrils in the parenchymal interstitium are extensions of the coarser fibers in the loose-binding connective tissue, stresses imposed at the alveolar wall level during lung inflation are transmitted not only to adjacent alveoli, which abut each other, but also to surrounding alveolar ducts and bronchioles, and then to the loose-binding connective tissue supporting the whole lobule, and ultimately to the visceral pleural surface (see Fig. 1-3). These relations become more apparent in certain pathologic conditions. For example, in interstitial emphy-

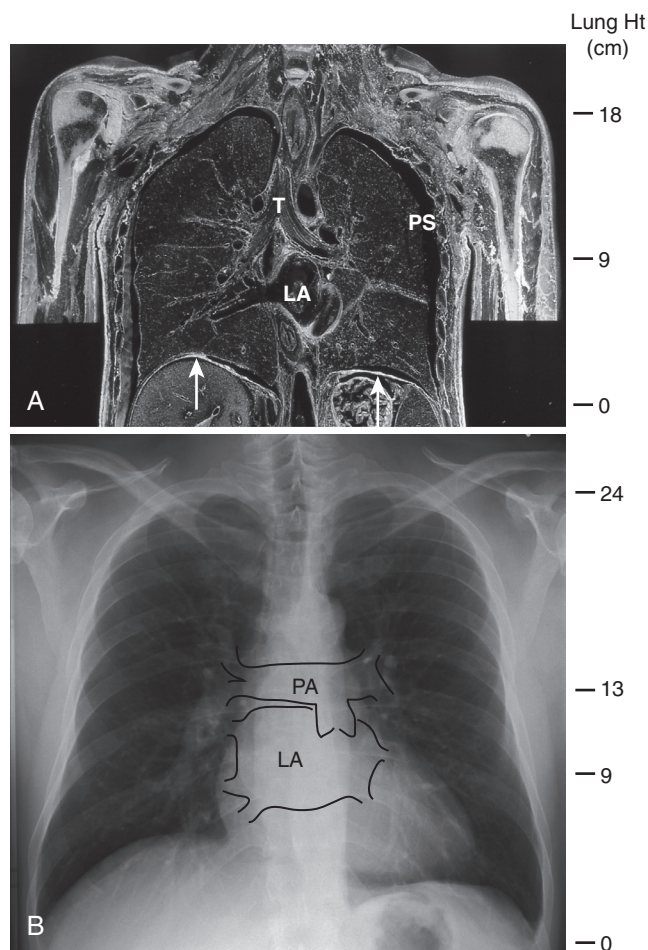

Figure 1-2 Comparison views of lung position in the chest and relationship to the heart. **A**, Midfrontal section through the thorax of a frozen cadaver of a 35-year-old human. The cadaver was prepared by routine embalming procedures, stored horizontally for 3 months in 30% alcohol, and frozen in the horizontal position for 1 week at -20°C . Frontal sections were cut with a band saw. Because the cadaver was preserved in the horizontal position, the weight of the abdominal organs compressed the contents of the thoracic cavity. The domes of the diaphragm (arrows) are elevated approximately 5 cm relative to their end-expiratory position in life. Pleural space (PS) width is artifactually enlarged; normally, in life, it is several micrometers in width. The trachea (T) is flanked on its left by the aortic arch and on its right by the azygos vein. The left pulmonary artery lies on the superior aspect of the left main-stem bronchus. Pulmonary veins from the right lung enter the left atrium (LA), which is located approximately 7 cm above the lung's base. These structures at the root of the lungs caused the esophagus to be cut twice as it follows a curved path behind them to reach the stomach. **B**, Chest radiograph of a normal human adult taken in the upright position at functional residual capacity. The lung height (cm) was measured from the costodiaphragmatic angle to the tubercle of the first rib. The main pulmonary artery (PA) and left atrium (LA) are outlined. The vascular structures, especially the pulmonary veins, are more easily seen near the bottom of the lung. This is partly because vascular distending pressures are greater near the bottom. The density of the lung is also graded, being higher at the bottom than the top and higher near the hilum than peripherally. (**A**, Reprinted with permission from Koritké JG, Sick H: *Atlas of sectional human anatomy*. Vol 1: Head, neck, thorax. Baltimore, 1988, Urban and Schwarzenberg, FT3a, p 83.)

sema,¹² air enters the loose-binding connective tissue and dissects along the peribronchovascular sheaths to the hilum and along the lobular septa to the visceral pleura. Interstitial pulmonary edema liquid enters and moves along the same interstitial pathways (Fig. 1-5).¹³

Table 1-1 Components of Normal Human Lung

Component	Volume or Mass (mL)	Thickness (μm)	Reference No.
Gas	2400		8
Tissue	900		3, 4
Blood	400		4
Lung	500		8
Support structures	225		5
Alveolar walls	275		5, 6
Epithelium	60	0.18	5, 6
Endothelium	50	0.10	5, 6
Interstitial	110	0.22	5, 6
Alveolar macrophages	55		6

Figure 1-3 General plan depicting the interstitial connective tissue compartments of the lung. All of the support structures (airways, blood vessels, interlobular septa, visceral pleura) are subsumed under the loose-binding connective tissue. The alveolar walls' interstitium comprises the parenchymal interstitium. This organizational plan of the lung follows the general organization of all organs. (Reproduced with permission from Hayek H: *The human lung*, New York, Hafner, 1960, pp 298–314.)

The bulk of the interstitium is occupied by a matrix of proteoglycans (Fig. 1-6).^{14,15} Proteoglycans constitute a complex group of gigantic polysaccharide molecules (≈ 30 different core proteins, with great diversity of glycosaminoglycan side chains) whose entanglements impart a gel-like structure to the interstitium. That structural role, although essential, is not the sole role of these important molecules. A growing view is emerging of the lung's extracellular matrix components as regulators of lung physiology, helping in determining epithelial cell phenotype; binding of and subsequent signaling by cytokines, chemokines, and growth factors; and mediating cell proliferation, migration, differentiation, and apoptosis.^{16–23} In disease states, degradation products of extracellular matrix components may activate the Toll-like receptor pathways (see later discussion); thus the degradation products may serve as endogenous

Figure 1-4 A drawing of the connective tissue support of the normal human adult lung lobule demonstrates the weave of fibers composing the “elastic continuum.” AD, alveolar duct; ALV, alveolus; IS, interstitial space; PA, pulmonary artery; PV, pulmonary vein; RB, respiratory bronchiole; TB, terminal bronchiole. (Reprinted with permission from Wright RR: Elastic tissue of normal and emphysematous lungs. *Am J Pathol* 39:355–367, 1961.)

Figure 1-5 Interstitial pulmonary edema demonstrating the loose-binding (peribronchovascular) connective tissue spaces (CTS) that surround the bronchi (Br) and pulmonary arteries (PA). Interstitial edema also expanded the interlobular septa (ILS) that are contiguous with the connective tissue of the visceral pleura (VP). (Frozen sheep lung, unstained.)

Figure 1-6 The interstitium. The connective tissue compartment of the lung contains interstitial cells (IC), fibrils of collagen (COL), and bundles of elastin (EL). The bulk of the interstitium, however, is occupied by matrix constituents (*) such as glycosaminoglycans. (Human lung surgical specimen, transmission electron microscopy.)

sentinels of tissue damage and initiators of innate immune responses.^{18,22–24} Within this gel-like interstitium reside several varieties of interstitial cells (contractile and noncontractile interstitial cells,^{25,26} mast cells, plasma cells, and occasional leukocytes). The remainder of the interstitium is

Figure 1-7 A bronchus. The bronchial wall is composed of mucosa (M), lamina propria (LP), smooth muscle (SM), and submucosa (S). Seromucous glands (G) are located between the spiral bands of smooth muscle and cartilaginous plates (CP). Diffuse lymphoid tissue (L) has infiltrated the lamina propria and submucosa. (Human lung surgical specimen, right middle lobar bronchus, 2-μm-thick glycol methacrylate section, light microscopy.)

Figure 1-8 A terminal bronchiole and respiratory bronchiole. The wall of the terminal bronchiole (TB) is constructed of a single layer of ciliated cuboidal epithelium that rests over thin, discontinuous bands of smooth muscle and loose areolar connective tissue (CT). In contrast, the wall of the respiratory bronchiole (RB) is only partially lined by ciliated cuboidal epithelium (lower left side). The remainder of its wall is lined by squamous epithelium (upper right side). The connective tissue also surrounds the adjacent pulmonary arteriole (PA). (Human lung surgical specimen, 10-μm-thick paraffin section, light microscopy.)

composed of laminin, collagens, elastin and reticulin fibrils, fibronectin, and tenascin (see Fig. 1-6).

AIRWAYS

The airways, forming the connection between the outside world and the terminal respiratory units, are of central importance to our understanding of lung function in health and disease. Intrapulmonary airways are divided into three major groups: *bronchi* (Fig. 1-7), *bronchioles* (including the terminal bronchioles) (Fig. 1-8), and *respiratory bronchioles* (Fig. 1-9; see Fig. 1-8). By definition, bronchi have cartilage in their wall, whereas bronchioles do not. Respiratory bronchioles serve a dual function as airways and as part of the alveolar volume (gas exchange).

Figure 1-9 Longitudinal sections along bronchioles. **A**, Diameter remains relatively constant along the terminal bronchiole (TB), respiratory bronchiole (RB), and alveolar duct (AD). Alveoli (A) communicate with the gas-exchange ducts (RB and AD). **B**, This longitudinal section along a respiratory bronchiole (RB) and alveolar duct (AD) also shows that their diameter is relatively constant and that both gas-exchange ducts communicate with clusters of alveoli (A). (Human lung surgical specimens, 10-μm-thick paraffin section, light microscopy.)

The anatomic dead space, as measured by the single-breath nitrogen dilution technique, is approximately 30% of each tidal volume. Anatomically this dead space is accounted for principally by the volume of the extrapulmonary (upper) airway, including the nasopharynx and trachea, and the intrapulmonary bronchi.²⁷ The trachea and bronchi are cartilaginous, do not change shape significantly with ventilation, and do not participate in gas exchange. Bronchioles, approximately 1 mm in diameter or less, have no cartilage and are exceedingly numerous and short. They consist of approximately five branching generations and end at the terminal bronchioles. In contrast to the bronchi, the bronchioles are tightly embedded in the connective tissue framework of the lung and therefore enlarge passively as lung volume increases.²⁸ Histologically the bronchioles down to and including the terminal bronchioles ought to contribute approximately 25% to the anatomic dead space. In life, however, they contribute little because of gas-phase diffusion and mechanical mixing in the distal airways resulting from the cardiac impulse. By definition, the respiratory bronchioles and alveolar ducts participate in gas exchange and thus do not contribute to the anatomic dead space. The volume of the respiratory bronchiole-alveolar duct system is approximately one third of the total alveolar volume, and it is into this space that the fresh-air ventilation enters during inspiration.

Most airway resistance resides in the upper airway and bronchi. Normally the large airways maintain partial constriction. The minimal airway diameter in the human lung,

Figure 1-10 Cross sections of two bronchioles (Brl) that would contribute to increased airway resistance. On the left is a bronchiole that is partially narrowed, evident by the folded and thick epithelium. The bronchiole to the right is completely narrowed. Its lumen is obliterated by the infolded epithelium. This bronchiole's smooth muscle is thick (arrow), suggesting that the narrowing is related to constriction of the smooth muscle. Each bronchiole is flanked by a pulmonary arteriole (PA). (Sheep lung, 5-μm-thick paraffin section, light microscopy.)

approximately 0.5 mm, is reached at the level of the terminal bronchioles; succeeding generations of exchange ducts (respiratory bronchioles and alveolar ducts) are of constant diameter (see Fig. 1-9).^{29,30} The functional significance of centralized resistance is that the terminal respiratory units (the physiologic alveoli) are regionally ventilated chiefly in proportion to their individual distensibilities (compliances) because most of their airway resistance is common. This is demonstrated normally by the finding that regional lung ventilation is dependent upon the initial volumes of the alveoli. Terminal respiratory units toward the top of the lung, which are more expanded at FRC, do not receive as great a share of the inspiratory volume as do the terminal respiratory units near the bottom of the lung.

The balance between anatomic dead space volume, for which the airway diameter ought to be as small as possible to maximize efficient alveolar ventilation (dead space-to-tidal volume ratio), and airflow resistance, for which the airway diameter ought to be as large as possible to minimize the work of breathing, requires a compromise. Normally, anatomic dead space is not maximal, nor is resistance minimal. In disease, by contrast, airways may narrow (Fig. 1-10), which increases resistance.

The cellular complexity of the airways is indicated by the nearly 50 distinct cell types found there, at least 12 of which are epithelial cells on the airway surface.³¹ Nearly half of the epithelial cells in the normal human airway are ciliated at all airway generations (Fig. 1-11) down to bronchioles (Fig. 1-12).³² Cilia move the superficial liquid lining layer (Fig. 1-13; see Fig. 1-11) continually toward the pharynx from deep within the lung. As the superficial lining liquid moves centripetally, the total perimeter of the airways decreases markedly.⁵ If the lining liquid volume remained constant, the liquid layer ought to thicken but this does not happen, suggesting that much of the liquid is reabsorbed during its ascent along the airways.

The presence of apical junctional complexes between airway epithelial cells (see Fig. 1-13) has important functional implications for metabolically-regulated secretion into and absorption of electrolytes and water from the lining liquid. Apical junctional complexes consist of three

Figure 1-11 The bronchial mucosa consists of pseudostratified, columnar epithelium with cilia (C) and goblet cells (black arrowhead). The cilia, which form a thick carpet, move rhythmically and thereby propel liquid, mucus, cells, and debris centrally toward the pharynx. The dark band immediately beneath the cilia (black arrow) is produced by the basal bodies. By transmission electron microscopy, basal bodies are recognized as modified centrioles. A lymphocyte (white arrowhead) is intercalated among the epithelial cells. A bronchial blood vessel (BV) is located beneath the mucosal layer. (Human lung surgical specimen, 10-μm-thick paraffin section, light microscopy.)

Figure 1-12 The respiratory bronchiole (RB)-alveolar duct (AD) junction is demarcated by an abrupt transition (arrowhead) from low cuboidal epithelial cells (E) with cilia to squamous epithelial cells. Submerged in the lining liquid (arrow) are an alveolar macrophage (AM) and cilia (Ci). Airway smooth muscle cells (SM) extend to this level of the airway tree. (Human lung surgical specimen, transmission electron microscopy.)

Figure 1-13 Cells constituting the bronchial epithelium are ciliated epithelial cells (CE), goblet cells (G), and basal cells (B). Goblet cells have abundant mucous granules in the cytoplasm, and their apical surface is devoid of cilia. Basal cells, as their name indicates, are located along the abluminal portion of the lining epithelium, adjacent to the basal lamina. The arrows at the apical surface of the airway cells indicate the location of junctional complexes between contiguous epithelial cells. (Human lung surgical specimen, transmission electron microscopy.)

Figure 1-14 Submucosal glands shown at a higher magnification view than in [Figure 1-7](#). These mixed, compound tubuloacinar glands contain mucus-secreting cells (M) and serous-secreting cells (S). The latter type form crescentic caps, or demilunes, over the ends of the acini. Mucus-secreting cells are the predominant glandular cell type.

elements: *zonula occludens* (tight junction), *zonula adherens*, and *macula adherens* (desmosome).³³ Tight junctions subserve two important functions: (1) restriction of passive diffusion by blocking the lateral intercellular space and (2) polarization of cellular functions (ion and water transport) between the apical and basolateral membranes.³⁴ Polarization of chloride and sodium transport allows the airway epithelium either to secrete or to absorb ions, with associated water movement.

Trapping of foreign material, such as particulates or bacteria, is accomplished by mucins. Mucins are complex glycoproteins that form gels, exemplified by MUC5A. MUC5A is present in the lung of humans.^{35,36} Other mucins (e.g., MUC5B, MUC7)^{37,38} become expressed by airway epithelial cells in diseases, such as cystic fibrosis. In that disease, MUC5B is produced by airway epithelial cells.³⁹ Normally MUC5B is produced by airway glandular cells,³⁷ but, in a variety of pulmonary diseases, its cell source is expanded.

Glands are limited to the submucosa of the bronchi. Airway glands secrete water, electrolytes, and mucins into the lumen ([Fig. 1-14](#); see [Fig. 1-7](#)). Studies of the regulation of secretion in vivo and in vitro have shown that release can be modulated by neurotransmitters, including cholinergic, adrenergic, and peptidergic transmitters,^{40,41} and by inflammatory mediators such as histamine,⁴² platelet-activating factor,⁴³ and eicosanoids.⁴⁴ Goblet cells, which are mucin-secreting epithelial cells, also are present at most airway levels (see [Fig. 1-13](#)). Goblet cells decrease in number peripherally, normally disappearing at terminal bronchioles.^{10,45} The absence of airway glands and goblet cells distal to ciliated epithelial cells makes sense because that arrangement should minimize the flow of mucus backward into alveolar ducts and alveoli.

Lymphocytes are frequently seen intercalated between airway epithelial cells ([Fig. 1-15](#); see [Fig. 1-11](#)). These cytotoxic T lymphocytes undergo IgA class antibody responses.⁴⁶ T and B lymphocytes also accumulate in the lamina propria beneath the airway epithelium.⁴⁷

Although most foreign material and immunologic stimuli are carried up the airways by mucociliary action, some are cleared by the lymphatics (discussed at the end of this chapter). In addition, lymphoid tissue is located in the lungs. Patches are distributed along the tracheobronchial

Figure 1-15 The terminal airway epithelium consists mainly of ciliated epithelium (CE) and nonciliated club cells (Clara) (CL). Club cells have the ultrastructural features of secretory cells; namely, they possess basally located rough endoplasmic reticulum, perinuclear Golgi apparatus, apically located smooth endoplasmic reticulum, and prominent membrane-bound granules (arrowheads). A lymphocyte (L) is intercalated among the epithelial cells. A small portion of a neuroendocrine cell (NEC) containing characteristic dense-cored vesicles is also visible at the base of the epithelial cells. (Human lung surgical specimen, transmission electron microscopy.)

tree (see [Fig. 1-7](#)) and, to a lesser extent, along the blood vessels.^{48,49} These patches apparently develop in response to antigenic stimulation because they are not present at birth in humans or in germ-free animals.^{48,49} Lymphocytes in these aggregates are principally B cells that express mainly IgA immunoglobulins.⁴⁷ The presence of lymphocytes along the airways provides a reminder that the respiratory system is constantly challenged by airborne immunologic stimuli. The tracheobronchial lymphoid tissue, including bronchus-associated lymphoid tissue, appears to provide an important locus for both antibody-mediated and cell-mediated immune responses. Another important locus of immune response is provided by the epithelial cells that line the airways and constitute the airway glands. Their importance stems from production of Toll-like receptors, whose role is identification of pathogen-associated molecular patterns.⁵⁰ Activation of Toll-like receptors leads to downstream signaling cascades that are involved in mucin production, leukocyte recruitment, antimicrobial peptide production, wound repair, and vascular formation.⁵¹⁻⁵⁵

Some of the other cells associated with the airways are smooth muscle cells, mast cells, basal cells, and club cells (Clara). Smooth muscle cells form circular bands around the airway epithelium as far peripherally as the respiratory bronchioles (see [Figs. 1-7](#) and [1-8](#)). Smooth muscle tone is

Figure 1-16 Mast cell (M) located adjacent to an airway. The mast cell flanks airway smooth muscle cells (SM). Granules in mast cells have heterogeneous morphologic characteristics, including whorled and scrolled contents (arrow). (Human lung surgical specimen, transmission electron microscopy.)

altered by the autonomic nervous system and by mediators released from mast cells, inflammatory cells, and neuroendocrine cells. During normal breathing, slight tonic contraction of small airway smooth muscle cells and reflex contraction of the larger airways stiffens them against external compression, as may result from forced expiration or coughing. The effector of these responses is the parasympathetic limb of the autonomic nervous system (vagus nerves). Therefore excessive vagal input causes severe contraction of airway smooth muscle and increases mucus secretion by submucosal glands, both of which limit airflow through conducting airways by decreasing airway lumen diameter and increasing airway resistance.

Mast cells in the human lung contain membrane-bound secretory granules that are characteristically filled by scrolled, crystalline, or particulate inclusions (Fig. 1-16). These granules contain a host of inflammatory mediators, including histamine, proteoglycans, lysosomal enzymes, and metabolites of arachidonic acid.⁵⁶ Not only can these mediators induce bronchoconstriction, they can also stimulate mucus production and induce mucosal edema by increasing permeability of bronchial vessels.

Basal cells are located along the basal lamina of airways (see Fig. 1-13). These small epithelial cells have been classically thought to be precursor cells for other airway epithelial cells, including ciliated cells.^{31,57} However, more recent experiments suggest that columnar secretory cells or club cells may also differentiate into ciliated epithelial cells following tissue injury.^{58,59}

Club cells (Clara), prominent in the terminal airways, are interspersed among the ciliated epithelial cells, are nonciliated, and have large apical granules (see Fig. 1-15).^{60,61} Club cells have at least four functions in the lung. One function is serving as progenitor cells for themselves and for ciliated epithelial cells.^{62,63} A second function is xenobiotic metabolism via the cytochrome P-450 monooxygenase system.⁶⁴⁻⁶⁷ A third function is secretion: club cells are a source of surfactant proteins (SPs; SP-A, -B, and -D)⁶⁸⁻⁷⁰ and also of lipids, proteins (club cell 10-kDa protein), glycoproteins, and modulators of inflammation (leukocyte protease inhibitor and trypsin-like protease).⁷¹⁻⁷³ A fourth function is liquid balance by influencing ion channels.^{74,75}

BRONCHIAL CIRCULATION

The trachea (and esophagus), main-stem bronchi, and pulmonary vessels into the lung (see Fig. 1-1), as well as the visceral pleura in humans (see “The Pleural Space and Pleuras” toward the end of this chapter), are supplied by the bronchial (systemic) circulation.^{45,76,77} Measurements of bronchial circulation, by microsphere studies in animals, indicate that flow is 0.5% to 1.5% of cardiac output and is predominantly to the large airways.^{45,76,78-81} The bronchial arteries arborize into bronchial capillaries that form a network in the lamina propria, in the submucosa, and in the region external to the cartilage of bronchi, as well as in the lamina propria of neighboring pulmonary arteries.⁸² Venous blood from the trachea and large airways enters bronchial venules, which converge to form bronchial veins that drain into the azygos or hemiazygos veins. Thus a substantial part of bronchial blood flow returns to the right side of the heart. Deeper in the lung, however, bronchial blood passes via short anastomotic vessels into the pulmonary venules, thus reaching the left side of the heart to contribute to the venous admixture.

The bronchial circulation has enormous growth potential, which is in contrast to the pulmonary circulation, which after childhood is unresponsive. In long-standing inflammatory and proliferative diseases, such as bronchiectasis or carcinoma, bronchial blood flow may be greatly increased.^{76,83} Scar tissue and tumors larger than 1 mm in diameter receive their blood supply via the bronchial circulation.^{84,85} The bronchial circulation is also the primary source of new vessels for repair of tissue after lung injury. As will be discussed near the end of this chapter, the bronchial circulation also supplies the visceral pleura of species that have thick visceral pleura, including humans.

PULMONARY CIRCULATION

In humans the pulmonary artery enters each lung at the hilum in a loose connective tissue sheath adjacent to the main bronchus (see Fig. 1-1). The pulmonary artery travels adjacent to and branches with each airway generation down to the level of the respiratory bronchiole (Fig. 1-17). The anatomic arrangements of the pulmonary arteries and the airways are a continual reminder of the relationship between perfusion and ventilation that determines the efficiency of normal lung function. Although the pulmonary veins also lie in loose connective tissue sheaths adjacent to the pulmonary artery and main-stem bronchus at the hilum, once inside the lung they follow Miller’s dictum⁴⁵ that the veins will generally be found as far away from the arteries and airways as possible. Peripherally, in the respiratory tissue the pulmonary arteries branch out from the core of the terminal respiratory unit, whereas the veins occupy the surrounding connective tissue envelope (Fig. 1-18). Each small muscular pulmonary artery supplies a specific volume of respiratory tissue, whereas the veins drain portions of several such zones.

Considerable quantitative data about the pulmonary circulation are available for the human lung (Table 1-2).⁸⁶⁻⁸⁸ Although most of the intrapulmonary blood volume is in

Figure 1-17 Divisions of the pulmonary artery (PA) travel beside the bronchi and bronchioles (Br) out to the respiratory bronchioles. Thus at all airway generations an intimate relationship exists with pulmonary arterial generations. Note that the loose-binding (peribronchovascular) connective tissue sheaths are not distended, compared to the interstitial edema cuffs in [Figure 1-5](#). (Frozen normal sheep lung, unstained.)

Figure 1-18 The terminal respiratory unit (the physiologist's alveolus) consists of the alveoli (A) and alveolar ducts (AD) arising from a respiratory bronchiole (RB). Each unit is roughly spherical, as suggested by the *dashed outline*. Pulmonary venules (PV) are peripherally located. PA, pulmonary artery; TB, terminal bronchiole. (Normal sheep lung, somewhat underinflated, 2-μm-thick glycol methacrylate section, light microscopy.)

Table 1-2 Quantitative Data on Intrapulmonary Blood Vessels in Humans

Vessel Class (with Diameter)	Volume (mL)	Surface Area (m ²)	Reference No.
Arteries (>500 μm)	68	0.4	86
Arterioles (13–500 μm)	18	1.0	86
Capillaries (10 μm)	60–200	50–70	87
Venules (13–500 μm)	13	1.2	88
Veins (>500 μm)	58	0.1	88

the larger vessels down to approximately 500 μm in diameter, nearly all of the surface area is in the smaller vessels. For example, the surface area of arterioles 13 to 500 μm in diameter exceeds that of the larger vessels by a factor of two, and the maximal capillary surface area is 20 times that of all other vessels.

Because the vertical height of the lung at FRC is 24 cm (see [Fig. 1-2](#)), the pressure within the pulmonary blood vessels varies by 24 cm H₂O over the full height of the lung. Thus, if pulmonary arterial pressure is taken as 20 cm H₂O (15 mm Hg, 1.9 kPa) at the level of the main pulmonary artery, which is halfway up the height of the lung, pressure in the pulmonary arteries near the top of the lung will be 12 cm H₂O, whereas pressure in pulmonary arteries near the bottom will be 36 cm H₂O. Pulmonary venous pressure, which is 8 cm H₂O at the level of the pulmonary artery in midchest (left atrial pressure), would be −4 cm H₂O near the top of the lung and +20 cm H₂O at the bottom. In the normal lung the blood volume is greater at the bottom because of increased luminal pressure, which expands those vessels and increases their volume. This effect of distention also decreases the contribution of the blood vessels at the bottom of the lung to total pulmonary vascular resistance.

From the time after birth through adulthood, the normal pulmonary circulation is a low-resistance circuit. The resistance is distributed somewhat differently, however, than in the systemic circulation, where the major drop in resistance is across the arterioles. Although the pressure drop along the pulmonary capillaries is only a few centimeters of water (similar to the pressure drop in systemic capillaries), the pulmonary arterial and venous resistances are low, so a relatively larger fraction of the total pulmonary vascular resistance (35% to 45%) resides in the alveolar capillaries at FRC.^{89,90} (For further information about pulmonary circulation in health and disease see Chapters 6 and 58.)

Vasoactivity plays an important part in the local regulation of blood flow in relation to ventilation.^{91,92} Because smooth muscle can be found in the pulmonary vessels on both the arterial and the venous side down to precapillary and postcapillary vessels,^{93,94} any segment can contribute to active vasomotion.⁹⁵ In pathologic conditions, vascular smooth muscle may extend down to the capillary level.^{96,97}

Theoretically, gas exchange may take place through the thin wall of almost any pulmonary vessel. At normal alveolar oxygen tensions, however, little oxygen and carbon dioxide is exchanged before the blood reaches the true capillaries.⁹⁸ In the pulmonary arterioles, because of their small volume (see [Table 1-2](#)), blood flow is rapid. As blood enters the vast alveolar wall capillary network, its velocity slows, averaging approximately 1000 μm/sec (or 1 mm/sec). Flow in the microcirculation is pulsatile because of the low arterial resistance.⁹⁹ Pulsations reach the microvascular bed from both the arterial and the venous sides. In fact, one sign of severe pulmonary hypertension is the disappearance of capillary pulsations.¹⁰⁰

The capillary network is long and crosses several alveoli ([Fig. 1-19](#)) of the terminal respiratory unit before coalescing into venules. The vast extent of the capillary bed together with the length of the individual paths means a reasonable transit time for red blood cells, during which gas exchange can take place. The anatomic estimate of

Figure 1-19 An alveolar capillary (C) is shared longitudinally along its path across three alveoli (A). The alveolar walls are flattened, and the wall junctions are sharply curved because the lung is fixed in zone 1 conditions. Some red blood cells remain in the capillary at an alveolar corner (arrow). (Perfusion-fixed normal rat lung, PAW = 30 cm H₂O, PPA = 25 cm H₂O, PLA = 6 cm H₂O, scanning electron microscopy. PAW, airway pressure; PLA, left atrial pressure; PPA, pulmonary artery pressure.)

approximately 0.5 to 1 second average transit time is essentially the same as that found using the carbon monoxide diffusing capacity method, in which one divides capillary blood volume by cardiac output to obtain mean capillary transit time.¹⁰¹ In the normal lung sufficient time is available for equilibrium between the oxygen and carbon dioxide tensions in the alveoli and the erythrocytes in the pulmonary capillaries. Only under extreme stress (heavy exercise at low inspired oxygen tensions) or in severe restrictive lung disease would the red blood cells be predicted to pass through the microcirculation without enough time to reach diffusion equilibrium.¹⁰²

Normally, capillary blood volume is equal to or greater than stroke volume. Under normal resting conditions, the volume of blood in the pulmonary capillaries is well below its maximal capacity, however. Recruitment can increase this volume by a factor of about three. Thus the normal capillary blood volume of 60 to 75 mL is one third of the capacity (200 mL) measured by quantitative histologic analysis.⁵

Anatomically, the pulmonary blood vessels can be divided into two groups in a manner similar to the connective tissue compartments: extra-alveolar and alveolar. *Extra-alveolar vessels* lie in the loose-binding connective tissue (peribronchovascular sheaths, interlobular septa). Extra-alveolar vessels extend into the terminal respiratory units. Arteries as small as 100 µm in diameter have loose connective tissue sheaths. This is in contrast to the bronchioles, which are tightly embedded in the lung framework from the bronchioles (1 mm in diameter) onward. *Alveolar vessels* lie within the alveolar walls and are embedded in the parenchymal connective tissue. They are subject to whatever forces operate at the alveolar level. They are referred to as alveolar vessels in the sense that the effective hydrostatic pressure external to them is alveolar pressure. Not all of the alveolar vessels are capillaries, however. Small arterioles and venules, which bulge into the air spaces, may be affected by changes in alveolar pressure. Likewise, not all of the capillary bed is alveolar under all conditions.¹⁰³ The corner capillaries in the alveolar wall junctions are protected from the full effects of alveolar pressure by the curvature and alveolar air-liquid

Figure 1-20 The thick (Tk) and thin (Tn) sides of an alveolar capillary (C) change as the capillary crosses between alveoli (A). The basal laminae of the capillary endothelium and alveolar epithelium fuse in the thin regions. The nucleus (Nu) of an endothelial cell (E) is visible above a red blood cell (R). I, alveolar type I cell. (Human lung surgical specimen, transmission electron microscopy).

surface tension.¹⁰⁴ This may account for the fact that, even under zone 1 conditions in which alveolar pressure exceeds both arterial and venous pressure, some blood continues to flow through the lung.¹⁰⁵ One has to go several centimeters up into zone 1 before blood flow stops completely. (For a discussion of distribution of pulmonary blood flow and lung zones, see Chapter 4.)

An important question is whether the normal human lung contains connections between the pulmonary arteries and veins that permit some portion of pulmonary blood flow to bypass the capillary network. Such vessels may develop congenitally or pathologically.¹⁰⁶ In the normal lung, however, functioning short circuits probably do not exist. (Pathologic arteriovenous communications are discussed in Chapter 61.)

Pulmonary capillaries are lined by continuous (non-fenestrated) endothelial cells (Fig. 1-20). These attenuated cells have an individual area of 1000 to 3000 µm² and an average volume of 600 µm³.¹⁰⁷ These large, flat cells cover a total surface area of approximately 130 m².¹⁰⁷ Other structural features of pulmonary capillary endothelial cells are the large number of plasmalemmal vesicles and small number of organelles (see Fig. 1-20). Despite having relatively few organelles, pulmonary capillary endothelial cells do have organelles involved in protein synthesis, such as endoplasmic reticulum, ribosomes and Golgi apparatus, and endocytosis (caveolae, multivesicular bodies, and lysosomes).¹⁰⁸ The endocytic apparatus appears to participate in receptor-mediated uptake and transport (transcytosis) of albumin, low-density lipoproteins, and thyroxine.¹⁰⁹⁻¹¹³ Another route for passage of solutes and water is between adjacent endothelial cells (transcellular transport). However, that passage route is restricted by specialized junctional complexes called “tight junctions.”^{114,115}

In addition to its function in gas exchange, the pulmonary circulation is involved in a number of other functions important to homeostasis. The pulmonary vascular bed serves as a capacitance reservoir between the right and left sides of the heart. Consequently, the reservoir of blood in the pulmonary circulation is sufficient to buffer changes in right ventricular output for two to three heartbeats. The

pulmonary vascular bed also serves as a filter, trapping any embolic material from systemic vascular beds. For example, during intravascular coagulation or in processes involving platelet or neutrophil aggregation, the predominant site of sequestration is the lung. The main anatomic reason for this is that 75% of the total circulating blood volume is in the venous circuit, and the lung's microvascular bed is the first set of small vessels through which the blood flows. Moderate numbers of microemboli generally produce no detectable dysfunction because of the huge array of parallel pathways in the microcirculation. At most, microemboli temporarily block flow to a portion of or to an entire terminal respiratory unit. The fate of such emboli is not clear. Some are phagocytosed and removed into the lung tissue.¹¹⁶ Some emboli can be degraded to a small size, pass through into the systemic circulation, and be removed by the reticuloendothelial system. One example of particulate matter that filters in the lung is the macroaggregated serum albumin used in lung-scanning procedures. (Further information about the pathophysiology of thromboembolic disorders is presented in Chapter 57.)

The endothelial cells of the pulmonary circulation are capable of a remarkable number of metabolic activities. This is not to say that endothelial cells in other organs do not have similar activities. But the central position of the lung, through which the entire cardiac output passes, places extra responsibility and extra importance upon its endothelial cells.¹¹⁷⁻¹¹⁹ For example, angiotensin I, bradykinin, and prostaglandin E₁ are nearly completely inactivated during a single pass through the lungs. Pulmonary endothelial cells also express at least two subtypes of endothelin receptors (A and C).¹²⁰⁻¹²² Their expression coincides with rapid removal of endothelin, suggesting that the lung microcirculation participates in clearance of this potent vasoconstrictor peptide from the blood. Conversely, a potent vasodilator, nitric oxide, is generated locally in the lung, through expression of endothelial nitric oxide synthase.¹²³⁻¹²⁹

Endothelial cells may have a role in regulating vascular tone and reactivity. An indication of this regulatory role can be seen in the direct contacts between pulmonary endothelial cells in small arteries and veins and the surrounding smooth muscle cells. Such myoendothelial contacts have been described in the lungs of a number of small animals,¹³⁰⁻¹³³ and we have seen them in the human lung (Fig. 1-21). Although their functional importance is unknown, they may have some bearing on endothelial-dependent vasoactivity.¹³⁴

Regulation of vasoactivity by endothelial cells may be facilitated by site-specific phenotypes of endothelial cells (reviewed by Garland and Dejana¹³⁵ and Gebb and Stevens¹³⁶). For example, endothelial nitric oxide protein is more evident in small pulmonary arterial vessels than in capillaries.¹²³⁻¹²⁸ Presumably the more evident localization reflects the functional role of nitric oxide in regulating pulmonary artery smooth muscle tone. On the other hand, capillary endothelial cells appear to have more expression-activated message for leukocyte adhesion molecules than arterial endothelial cells.^{135,136} Greater expression by capillary endothelial cells may contribute to sequestration of leukocytes in the capillary bed during acute inflammatory reactions. Another endothelial cell function that is site specific in the lung is Ca²⁺ transients that are induced by pres-

Figure 1-21 A myoendothelial cell contact (arrow) is made between a pulmonary arteriolar (PA) endothelial cell (E) and a subjacent vascular smooth muscle cell (SM). The distribution and functional significance of such contacts is unknown. One potential role may be to facilitate delivery of endothelium-derived relaxing factor to smooth muscle cells. Nu, nucleus of the endothelial cell. (Human lung surgical specimen, transmission electron microscopy).

sure elevations as small as 5 cm H₂O. The calcium transients seen in a subset of Ca²⁺ oscillating cells are referred to as “pacemakers” and are located in pulmonary venular capillaries.¹³⁷ The oscillations are propagated to adjacent endothelial cells. This endothelial response may be relevant in the pathogenesis of pressure-induced lung microvascular injury.

TERMINAL RESPIRATORY UNITS

The “alveolus” of which the physician or pulmonary physiologist speaks is referred to as the “terminal respiratory unit” by the anatomist. The terminal respiratory unit consists of all the alveolar ducts, together with their accompanying alveoli, that stem from the most proximal (first) respiratory bronchiole (see Fig. 1-18). The terminal respiratory unit has both a structural and a functional existence and was first described by Hayek.¹⁰ In the human lung this unit contains approximately 100 alveolar ducts and 2000 alveoli. At FRC the unit is approximately 5 mm in diameter, with a volume of 0.02 mL. In normal adult humans, there are approximately 150,000 such units in both lungs combined.⁵ The acinus, an anatomic unit popular among pathologists, contains 10 to 12 terminal respiratory units.¹³⁸⁻¹⁴⁰

The functional definition of the terminal respiratory unit is that, because gas phase diffusion is so rapid, the partial pressures of oxygen and carbon dioxide are uniform throughout the unit.¹⁴¹ Diffusion is the name for a thermodynamic process by which molecules express their kinetic energy. Net diffusion takes place when a concentration difference of a substance exists between two volumes. Thus oxygen in the alveolar duct gas will diffuse into the alveoli, because the incoming air has a higher oxygen concentration than the alveolar gas. Oxygen will also diffuse from the gas adjacent to the alveolar wall through the air-blood barrier into the red blood cells flowing in the capillaries (Fig. 1-22), where oxygen combines with hemoglobin. Carbon dioxide diffuses in the opposite direction. A key point about

Figure 1-22 Cross section of an alveolar wall showing the path for oxygen and carbon dioxide diffusion. The thin side of the alveolar wall barrier (short double-headed arrow) consists of type I epithelium (I), interstitium (*) formed by the fused basal laminae of the epithelial and endothelial cells, capillary endothelium (E), plasma in the alveolar capillary (C), and finally the cytoplasm of the red blood cell (R). The thick side of the gas-exchange barrier (long double-headed arrow) has an accumulation of elastin (EL), collagen (COL), and matrix that jointly separate the alveolar epithelium from the alveolar capillary endothelium. As long as the red blood cells are flowing, oxygen and carbon dioxide probably diffuse across both sides of the air-blood barrier. A, alveolus; Nu, nucleus of the capillary endothelial cell. (Human lung surgical specimen, transmission electron microscopy.)

diffusion is that the process is much faster in the gas phase than in water. Thus the terminal respiratory unit size is defined in part by the fact that gas molecules can diffuse and equilibrate anywhere within the unit more rapidly than they can diffuse through the membrane into the blood. The main problem is that the solubility of oxygen in water is low relative to its concentration in gas. Water becomes a problem when edema liquid accumulates in alveoli and/or interstitium in the alveolar walls. Carbon dioxide is much more soluble in water (20 times the solubility of oxygen in water), and therefore carbon dioxide diffuses rapidly into the gas phase, even though the driving pressure for carbon dioxide diffusion is only one tenth that for oxygen entering the blood.

It is almost impossible to demonstrate that diffusion is limiting in the normal lung, except during heavy exercise while breathing gas containing very low oxygen concentrations.¹⁰² Even then, diffusion limitation may not be as important as the reduced transit time of the red blood cells. However, apart from these observations during heavy exercise, most disorders of oxygenation are due to ventilation-perfusion inequalities.¹⁴²

All portions of the terminal respiratory unit participate in volume changes with breathing.^{143,144} Thus, if a unit were to increase its volume from FRC, the alveolar gas that had been in the alveolar duct system would enter the expanding alveoli, together with a small portion of the fresh air. Most of the fresh air would remain in the alveolar duct system. This does not lead to any significant gradient of alveolar oxygen and carbon dioxide partial pressures because diffusion in the gas phase is so rapid that equilibrium is established within a few milliseconds. But nondiffusible (suspended or particulate) matter would remain away from the alveolar walls and be expelled in the

subsequent expiration.¹⁴⁵ This explains why it is difficult to deposit aerosols on the alveolar walls and why large inspired volumes and breath-holding are important for obtaining efficient alveolar deposition.

The anatomic alveolus is not spherical (Fig. 1-23; see Fig. 1-19). It is a complex geometric structure with flat walls and sharp curvature at the junctions between adjacent walls. The most stable configuration is for three alveolar walls to join together, as in foams.⁵ The resting volume of an alveolus is reached at minimal volume, which is 10% to 14% of total lung capacity. When alveoli go below their resting volume, they must fold up because their walls have a finite mass. Most of the work required to inflate the normal lung is expended across the air-liquid interface to overcome surface tension; the importance of the air-liquid interface is demonstrated by the low pressure required to “inflate” a liquid-filled lung with more liquid.¹⁴⁶

The phenomenon of terminal respiratory unit, or alveolar, stability is confused because not only is air-liquid interfacial tension involved, but each flat alveolar wall is part of two alveoli and both must participate in any change. Therefore atelectasis does not usually involve individual alveoli but rather relatively large units (Fig. 1-24).¹⁴⁷

The alveolar walls are composed predominantly of pulmonary capillaries. In the congested alveolar wall, the blood volume may be more than 75% of the total wall volume. Alveoli near the top of the lung show less filling of the capillaries than those at the bottom.^{148,149} This affects regional diffusing capacity, which is dependent on the volume of red cells in the capillaries (see also eFig. 25-10).

The transition from the cuboidal epithelium of the respiratory bronchiole to alveolar squamous epithelium is abrupt (see Fig. 1-12). Although Macklin¹⁵⁰ speculated that the permeability of the bronchiole-alveolar epithelial junctions may be special, no definitive difference has been demonstrated.¹⁵¹ The controversy continues as to whether this region shows unique permeability features that might participate in clearance of particles or leakage of edema.¹⁵²⁻¹⁵⁴

The pleomorphic nature of the alveolar epithelium and the light and electron microscopic structure of its constituent cells have been described many times and will be only briefly summarized here. In normal mammals and other air-breathing species, including reptiles and amphibians, the alveolar epithelium is composed of cuboidal alveolar type II cells and flattened type I cells (Fig. 1-25). Alveolar type II cells outnumber type I cells ($\approx 15\%$ versus 8% to 10% of total peripheral lung cells, respectively), but type I cells account for approximately 90% to 95% of the alveolar surface area of the peripheral lung.¹⁵⁵ The two cell types have different functions and structure.

The alveolar type II cell is the major synthesizing and secreting factory of surfactant-associated proteins that affect adsorption of surfactant lipids to an air-liquid interface, surfactant recycling, and immunomodulatory functions. Alveolar type II cells also express receptors for several growth factors and secretagogues, enzymes, matrix proteins, and epithelial mucins.¹⁵⁶⁻¹⁶¹ The presence of various ion channels and transporters supports earlier evidence that alveolar type II cells are actively involved in liquid resorption and transepithelial water fluxes.¹⁶² Alveolar type II cells are reported to express some species of aquaporin

Figure 1-23 Alveolar shape changes at representative points along the air deflation pressure-volume curve of the lung. The four micrographs are at the same magnification. The air deflation pressures are as follows: **A**, 30 cm H₂O (total lung capacity; TLC); **B**, 8 cm H₂O (approximately 50% TLC); **C**, 4 cm H₂O (near functional residual capacity; FRC); and **D**, 0 cm H₂O (minimal volume). Vascular pressures are constant (PPA = 25 cm H₂O and PLA = 6 cm H₂O). Intrinsic alveolar shape (AI) is maintained from TLC to FRC (**A–C**). The alveolar walls are flat, and there is sharp curvature at the junctions between adjacent walls. Note the flat shape of the alveolar capillaries (*arrow*) at TLC (**A**, lung zone 1 conditions) compared to their round shape (*arrow*) at FRC (**C**, lung zone 3 conditions). The alveolar walls are folded, and alveolar shape is distorted at minimal lung volume (**D**). The *arrow* in **B** identifies an alveolar type II cell at an alveolar corner. The *arrowhead* in **B** identifies a pore of Kohn. PAW, airway pressure; PLA, left atrial pressure; PPA, pulmonary artery pressure. (Perfusion-fixed normal rat lungs, scanning electron microscopy.)

Figure 1-24 Histologic appearance of atelectasis. Atelectasis usually involves relatively large units of lung parenchyma, rather than individual alveoli. Alveolar walls in the atelectatic units are folded, distorting the shape of alveoli and capillaries, as shown in [Fig. 1-23D](#). (Sheep lung injured by air emboli, 2-µm-thick glycol methacrylate section, light microscopy.)

Figure 1-25 Cells of the terminal respiratory unit. An alveolar macrophage (M) is located in an alveolus (A). Alveolar macrophages are the air space scavengers that are cleared either up the mucociliary escalator or into the interstitium. These cells can be activated to express and secrete cytokines, which may interact with other cells. Cells of the alveolar wall are the lining alveolar type I and II cells (I and II, respectively) and the enclosed capillary (C), endothelial cells (E), and interstitial cells (IC). (Human lung surgical specimen, transmission electron microscopy.)

Figure 1-26 **A**, Alveolar type II (or granular) cells (II) are cuboidal epithelial cells that contain characteristic lamellar bodies (LB) in their cytoplasm and have stubby microvilli (Mv) that extend from the apical surface into the alveolar air space (AS). Other prominent cytoplasmic organelles in alveolar type II cells are mitochondria (Mi) and Golgi apparatus (G). Adjacent to the type II cell is a process of a type I cell (I). The abluminal surface of the epithelial cells rests on a continuous basal lamina (arrowhead). Nu, nucleus of an alveolar type II cell. **B**, The apical region of an alveolar type II cell has two lamellar bodies (LB), one of which has been fixed in the process of secretion by exocytosis (arrows). The lamellar osmophilic bodies are believed to be the source of surface-active material (surfactant). Alveolar type II cells are usually located in the alveolar corners (see Fig. 1-23B). (Human lung surgical specimen, transmission electron microscopy.)

(AQP3, AQP1),^{163,164} water channels that may facilitate transepithelial liquid fluxes.

The typical alveolar type II cell (e.g., human, rodent) is a small (300 μm^3), cuboidal cell with short stubby apical microvilli (Fig. 1-26). The distinguishing structural feature of an alveolar type II cell is its content of intracellular lamellar bodies, which are membrane-bound inclusions (diameter from <0.1 to 2.5 μm ; mean, $\approx 1 \mu\text{m}$) composed of stacked layers of cell membrane-like material (see Fig. 1-26). These bodies contain pulmonary surfactant and are composed of phospholipid species similar to those of lavaged surfactant.¹⁶⁵ Lamellar bodies also contain various proteins, including SP-A, SP-B, and SP-C but probably not SP-D, typical lysosomal enzymes, an H^+ transporter, a unique α -glucosidase, and other molecules.¹⁶⁶⁻¹⁶⁸ Alveolar type II cells also internalize and recycle surfactant lipids and proteins, but the cellular pathways are not well characterized in terms of participating organelles, signaling mecha-

nisms, and general molecular regulation. Multivesicular bodies, organelles generally involved in endocytosis, are unusually abundant in alveolar type II cells and also express the ABC-type transporter membrane protein.¹⁶⁹

Alveolar type I cells have extensive, attenuated cytoplasmic processes that form a large, thin surface area for gas exchange (see Fig. 1-25). The enormous surface area of these cells presents a logistical problem for transport of new proteins and other substances within the cell over long distances and most likely contributes to the vulnerability of the type I cell to injury. Under normal conditions, alveolar type I cells attach via tight junctions to neighboring alveolar type II cells to form a relatively impermeable seal between alveolar air and alveolar wall interstitial spaces. Although the cells express connexin proteins used to form gap junctions,¹⁷⁰ such junctions have not been consistently observed by electron microscopy. Lectin-binding and histochemical studies show that the chemical nature of the alveolar type I cell apical membrane differs markedly from that of type II cells, and this concept is confirmed by the identification of novel type I cell proteins. The alveolar type I cell protein aquaporin-5 is of particular interest because this water channel has the highest water permeability known, at least in vitro.¹⁷¹ Type I cells also express epithelial Na^+ channels and membrane Na^+, K^+ -ATPase.^{172,173} These observations collectively imply that type I cells may play a role in pulmonary water flux, although this is not yet proven.^{174,175}

Alveolar type I cells contain many small, non-clathrin-coated vesicles, or caveolae, that are open either to the alveolar lumen or interstitium or are detached from the surface as free vesicles in the cytoplasm.¹⁷⁶ Immunohistochemistry shows that the vesicles contain caveolin-1 protein.¹⁷⁷ Likewise, biochemical analyses¹⁷⁸ show high concentrations of caveolin protein and messenger RNA in lung where it is expressed mainly by type I and vascular endothelial cells. Caveolin-1 is a scaffolding protein that organizes specialized membrane phospholipids and proteins into vesicles. Caveolin-1 can bind free cholesterol and modulate the efflux of cholesterol from the cell when intracellular concentrations rise,¹⁷⁹ and, in other cell systems, its expression is tightly linked to the availability of free cholesterol. Caveolae appear to sequester various proteins into the vesicles; such proteins include growth factor receptors, signaling molecules such as G proteins, Ca^{2+} receptors and pumps, and, in endothelial cells, endothelial nitric oxide synthase. The general effect of sequestration of receptors and signaling molecules into caveolae is to maintain them in a functionally quiescent state.

Trapping and clearance of particulate matter impinging on the alveolar surfaces is vital and takes place in the alveolar surface liquid. Within this liquid are suspended alveolar macrophages (see Fig. 1-12). The cytoplasm of alveolar macrophages contains numerous storage granules that are blackened by ingested particulate matter that reach the alveoli (see Fig. 1-25). Alveolar macrophages actively express and secrete cytokines, such as tumor necrosis factor- α and transforming growth factor- α , that are important for innate immunity. Some of these alveolar macrophages penetrate into the lung interstitium and can be seen as deposits of black pigment within interstitial foci. The majority of alveolar macrophages that reach the terminal airways via the slow, upward flow of alveolar lining liquid

Figure 1-27 Surface view of the visceral pleura. Yellow latex polymer (Microfil) was perfused through the bronchial artery trunk to fill the bronchial arteries (BA) that supply the visceral pleura. Bronchial arterioles flank lymphatics (arrow) that constitute the superficial lymphatic plexus of the lung. (Sheep whole lung, macroscopic view).

are expelled with the surface film as it is pulled up onto the mucociliary escalator.¹⁸⁰⁻¹⁸²

LYMPHATICS

Another route for clearance of particulate matter and liquid from the lung is the pulmonary lymphatic system. Lymphatics of the lung are subdivided into two principal groups based on their location: a deep plexus and a superficial plexus.^{10,45,183,184} Both plexuses are made up of initial and collecting lymphatics, with communications between the two.^{10,45,153,183} The *deep plexus* is situated in the peribronchovascular connective tissue sheaths of the lung (see Fig. 1-1).^{10,45,153,183} Lymphatics in the deep plexus are distributed around the airways, extending peripherally to the respiratory bronchioles and next to branches of the pulmonary arteries and veins.^{10,45,153,183} The *superficial plexus* is located in the connective tissue of the visceral pleura (Fig. 1-27). This plexus is prominent in the lung of species with thick visceral pleura, including humans (see “*The Pleural Space and Pleuras*”).^{10,45,183} Lymphatics are not found in the alveolar walls.

Lymph is propelled centripetally toward the lung's hilum or pulmonary ligament to reach regional lymph nodes. In the human, pulmonary lymph flows to extrapulmonary lymph nodes located around the primary bronchi and trachea.^{10,45,183}

INNERVATION

Innervation of the human lung consists of sensory (afferent) and motor (efferent) pathways.^{183,185-187} The sensory pathways originate in relation to the airway epithelium, submucosa, interalveolar septa, and smooth muscle. Mapping the complete distribution of the mucosal sensory nerve endings has been hampered by the lack of dependable morphologic methods that identify intraepithelial sensory axons. Ultrastructural techniques have shown that axons, when found, resemble known sensory endings in other organs (<1 μm in diameter, electron lucent, and containing microtubules and smooth endoplasmic reticulum).¹⁸⁸ Fibers of this pathway include myelinated, slowly adapting stretch

Figure 1-28 Unmyelinated axons (UA) known as C fibers are shown situated in the interstitium of a respiratory bronchiole, between an alveolar type I cell (I) lining an alveolus (A) and an initial lymphatic (L). Although the presence of small clear vesicles is suggestive of cholinergic (autonomic) axons, unequivocal identification as either motor or sensory fibers is not possible in random thin sections. E, lymphatic endothelial cell. (Human lung surgical specimen, transmission electron microscopy.)

receptors (Hering-Breuer reflex) and irritant receptors, but most are unmyelinated, slow-conducting C fibers located in the terminal respiratory units, either along the bronchioles or within the alveolar walls (Fig. 1-28). There has been speculation about the function of C fibers since Paintal first suggested that they played a role in sensing parenchymal connective tissue distortion, as during pulmonary vascular congestion and interstitial edema.¹⁸⁹⁻¹⁹² The speculation has been neither proven nor disproven.

Chemosensory cells are also present in the upper and lower airways.^{193,194} This sensory role is subserved in the human lung by ciliated airway epithelium of the upper and lower airways, which have functional components for bitter taste receptors.¹⁹⁵ In addition, solitary epithelial brush cells with a chemosensory function are present in upper and lower airways.¹⁹⁶ The afferent fibers travel in the vagus nerves and terminate in the vagal nuclei in the medulla oblongata.¹⁹⁷

Submucosal sensory nerve endings, in contrast, are more reliably identifiable because the axon can be stained with methylene blue or silver nitrate. Furthermore, studies of axonal transport indicate that the peripheral processes of sensory ganglia project to the submucosa.¹⁹⁸ Ultrastructural observations of these fibers reveal axonal terminals containing numerous membranous inclusions and mitochondria, which are characteristic of mechanoreceptors.

The motor pathways reach the lung through the sympathetic and parasympathetic nervous systems. Preganglionic contributions to the sympathetic nerves arise from the upper four or five thoracic paravertebral ganglia, whereas the preganglionic parasympathetic nerves originate in the brain stem motor nuclei associated with the vagus nerves. Postganglionic sympathetic nerve fibers terminate near an airway, innervating vascular smooth muscle cells and submucosal glands. Postganglionic parasympathetic fibers extend from ganglia mainly located external to the smooth muscle and cartilage. Some submucosal ganglia exist, but they are generally smaller and have fewer neurons.

Mucosal motor nerve endings also exist.¹⁹⁹ Characteristic ultrastructural features are axonal profiles containing many small, agranular vesicles and few mitochondria.

Unfortunately, the source and function of these axons is unknown. A goblet cell secretomotor role is doubtful because goblet cells in isolated epithelial strips do not secrete glycoproteins when bathed in drugs that mimic neurotransmitters.²⁰⁰ Alternatively, a role may be the release of mucus by direct response to mechanical and chemical signals. Another effector role of nerves in the lung is epithelial ion transport, a process that is stimulated by catecholamines,²⁰¹ acetylcholine,²⁰² and neuropeptides.²⁰³ This role is further supported by the presence of α -adrenergic, β -adrenergic, and muscarinic receptors throughout the airway epithelium.²⁰⁴

Submucosal tracheal gland efferent nerve endings consist of cholinergic, adrenergic, and peptidergic axonal profiles.^{205,206} Discrimination among these axonal types is partially aided by their ultrastructural appearance: cholinergic axons have small, agranular vesicles; adrenergic axons have small, dense-cored vesicles; peptidergic axons have many large, dense-cored vesicles. One must realize, however, that these descriptive definitions are not absolutely reliable.

The lung also contains a component of the diffuse neuroendocrine system called the amine uptake and decarboxylation system.^{207,208} Despite the growing recognition that a diffuse neuroendocrine system is located in the lung, we do not understand its normal functional role, although one can postulate that these cells release hormones that affect smooth muscle.^{209,210} This system is composed of single neuroendocrine cells and clusters of such cells, known as neuroepithelial bodies, distributed along the airway epithelium to the region of alveolar ducts.²¹¹⁻²¹⁴ The neuroepithelial bodies are preferentially located at airway bifurcations. Pulmonary neuroendocrine cells are ultrastructurally characterized by dense-cored vesicles in their cytoplasm (Fig. 1-29). The dense-cored vesicles are considered to be the storage sites of amine hormones (serotonin, dopamine, norepinephrine) and peptide hormones (bombesin, calcitonin, leu-enkephalin).²¹⁵ Neurons are also associated with the airway epithelial and neuroendocrine cells; they appear to be the storage sites for vasoactive intestinal peptide^{215,216} and substance P.^{217,218}

Figure 1-29 Neuroepithelial body (NEB) located in a peripheral airway. Neuroepithelial bodies contain aggregates of neuroendocrine cells. A characteristic ultrastructural feature of neuroendocrine cells is the presence of small (0.1 to 0.3 μm in diameter) dense-cored vesicles in their cytoplasm (arrow). Each dense-cored vesicle is bounded by a unit membrane. (Human lung surgical specimen, transmission electron microscopy.)

THE PLEURAL SPACE AND PLEURAS

As stated at the outset of this chapter, the primary function of the lung is ventilation-perfusion matching, ensuring efficient gas exchange between alveolar air and alveolar capillary blood. This vital function is met, in part, by extensive and rapid movement of the lung within the pleural space and its pleural liquid.^{219,220} Online supplemental digital videos linked to this chapter provide a glimpse of the view that surgeons have during dissection through the intercostal muscles: the lungs glide along the deep surface of the translucent endothoracic fascia and parietal pleura (see Videos 1-1 to 1-5). The pleural space also serves as an outlet into which pulmonary edema liquid can escape.^{221,222} The pleural liquid also serves to couple the lung to the chest wall.²²³ What are the anatomic features of the pleural space and pleuras that contribute to these functions?

An important anatomic fact is that the pleural space is a real space (Fig. 1-30); it is not a potential space.^{2,223} The pleural space surrounds the lung, except at its hilum, where the parietal pleura and visceral pleura are contiguous.^{10,116} Separations are present between the parietal and visceral pleuras along the interlobar fissures and costodiaphragmatic recesses. The normal volume of pleural liquid is 0.1 to 0.2 mL/kg body weight in most mammals.^{223,224} This specific volume is distributed across a pleural surface area of approximately 1000 cm^2 per lung and pleural space width of 10 to 20 μm (see Fig. 1-30).^{2,223} Normally there is little or no contact across the pleural space because the microvilli that extend from the parietal and visceral mesothelial cells are only 3 to 5 μm long.^{1,2,225,226}

Visceral pleural anatomy is characterized by a single layer of mesothelial cells that have microvilli extending from their surface into the pleural space.²²⁵ However, the thickness of the visceral pleura is not uniform across species (Fig. 1-31). Visceral pleural anatomy is characterized as

Figure 1-30 The pleural space is a real space. The dark band delimited by the opposed arrows is the pleural space, which is located between the chest wall and lung. (Frozen sheep chest wall and lung, unstained.)

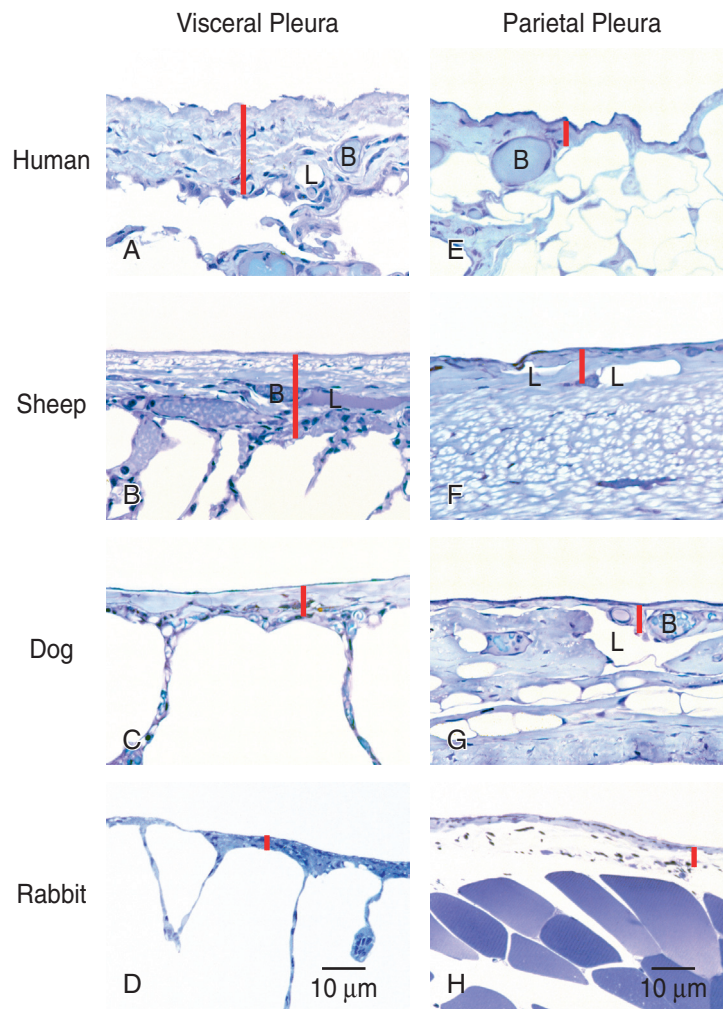

Figure 1-31 Comparative histologic features of the visceral and parietal pleuras among humans, sheep, dogs, and rabbits. The eight panels are shown at the same magnifications. **A–D**, Visceral pleura. **E–H**, Parietal pleura. The most obvious feature of the visceral pleura is its greater thickness (*longer red vertical bars*) in humans and sheep compared to the thinner visceral pleura of dogs and rabbits (*shorter red vertical bars*). The parietal pleura is thinner and consistently so among all the same species. Both the visceral and parietal pleuras are lined by a single layer of mesothelial cells that have microvilli extending from their surface into the pleural space. Subjacent to the mesothelial cell lining layer is loose areolar connective tissue. Among species with “thick” visceral pleura, the loose areolar connective tissue is traversed by bronchial microvessels (B), lymphatics (L), and nerves. By comparison, among species with “thin” visceral pleura, the loose areolar connective tissue is devoid of microvessels, other than the subjacent pulmonary microvessels at the perimeter of the most superficial alveoli. Lymphatics and nerves are infrequent. In the parietal pleura’s loose areolar connective tissue are systemic blood microvessels (B), lymphatics (L), and nerves. This histologic organization is consistent among species. (Human, sheep, dog, and rabbit lung, 2- μ m-thick glycol methacrylate sections, light microscopy.)

“thick” or “thin.”²²⁷ Species with a thick visceral pleura (range is 25 to 100 μ m) are humans, sheep, cows, pigs, and horses.²²⁵ Species with a thin visceral pleura (range 5 to 20 μ m) are dogs, rabbits, rats, and mice.²²⁸ The variability in thickness is related to the connective tissue layer beneath the visceral pleural mesothelial cells. The other anatomic difference among species with thick or thin visceral pleura is their arterial blood supply. Species with a thick visceral pleura has an arterial blood supply from the systemic circulation, via bronchial arteries (see Fig. 1-27).^{45,183,225,227} By comparison, species with a thin visceral pleura has an arterial blood supply from the pulmonary circulation. The reason for this striking difference in visceral pleural anatomy among mammals is not known.

Parietal pleural anatomy is also characterized by a single lining layer of mesothelial cells with microvilli extending

from their surface.²²⁶ The thin subjacent loose areolar connective tissue layer contains systemic blood vessels, lymphatics, and nerves. Unlike the situation with the visceral pleura, this thin histologic organization of the parietal pleura is consistent among species, including humans (see Fig. 1-31).^{10,116,226,229,230}

The unique anatomic features of the parietal pleura are the lymphatic stomata.^{226,230-233} They are openings (\approx 1 to 3 μ m in diameter) between parietal mesothelial cells (Fig. 1-32). Tracer studies revealed that India ink and chicken red blood cells (which are nucleated and therefore easily identifiable) are cleared almost exclusively from the pleural space by the stomata, which are located over the intercostal spaces in the distal half of the thorax, and along the sternum and pericardium of experimental animals that have been studied.^{226,229} The openings are continuous with

Figure 1-32 Surface view of lymphatic stomata, initial lymphatics, and collecting lymphatics of the parietal pleura. **A** and **B** are scanning electron micrographs that show the unique structure of lymphatic stomata (S). Stomata are apertures between the pleural space and the initial lymphatics in the parietal pleura. Three stomata are visible in a low-magnification field of view in **A**. Stomata are located over intercostal muscles. **B** shows a different stoma at a higher magnification. Microvilli are not present at the aperture of stomata, which are lined by mesothelial cells. **C** shows a portion of the parietal pleura where colloidal carbon is seen in four beds of initial lymphatics (arrows) that are located over an intercostal space. Colloidal carbon is also in collecting lymphatics (L) that cross a rib, where the collecting lymphatics drain into lymphatic vessels that accompany the intercostal vessels. (Rabbit, macroscopic view of the parietal pleura after colloidal carbon was placed in the pleural space in situ.)

the lumen of lymphatic capillaries. Physiologic studies showed that protein and particulate matter in the pleural space are cleared almost exclusively by the parietal pleural system of stomata and lymphatics.^{231,234} The lymphatics convey the pleural liquid to regional lymph nodes along the sternum and vertebral column; from there, lymph is carried

to the thoracic duct and right lymphatic duct. In this regard, normal pleural liquid is cleared by mechanisms that are consistent with normal interstitial liquid turnover in tissues throughout the body.

COMPARISON OF THE LUNG OF MICE AND HUMANS

A point made in the previous section is that species variations are significant in visceral pleural structure and blood supply. This point raises a question of what other species variations are found in the lung. For the purpose of this chapter, comparison is made between mouse and human, owing to the fantastic discoveries about genetic and molecular regulation of lung biology by making mouse constructs to identify normal lung structure and function, as well as to study the impact of disease on lung structure and function. Key structural features of mouse and human pulmonary morphology are summarized in [Table 1-3](#).²³⁵⁻²³⁷ This table reveals that many anatomic and developmental differences are present that may be helpful to keep in mind.

In the mouse lung, in contrast to the human, the walls of intrapulmonary conducting airways do not have cartilage, which may affect the distribution of airway resistance compared to the human lung ([Fig. 1-33](#)). In addition, in the mouse lung, respiratory bronchioles are essentially absent, whereas the human lung has approximately 150,000 respiratory bronchioles (see [Fig. 1-33](#)). Thus the mouse lung has fewer airway generations and a significantly smaller total surface area for gas exchange than the human lung. Another potential impact of the fewer airway generations, as well as narrower conducting airways, is that the deposition of inhaled particulates may have a different distribution in the lungs of mice compared to those of humans. Also, because the mouse lung has fewer airway generations, the parenchyma makes up a larger proportion of total lung volume in mice ($\approx 18\%$) compared to humans ($\approx 12\%$).

Another notable species difference is the distribution of various cell types. In the upper airway of the human lung, the principal secretory cells are goblet cells (see [Fig. 1-13](#)), whereas in the upper airway of the mouse lung, the principal secretory epithelial cells are the club cells (Clara). Club cells in the human lung are found in the terminal airways (see [Fig. 1-15](#)). In addition, in the upper airway of the human lung, additional secretory cells are mucous and serous epithelial cells in submucosal glands (see [Figs. 1-14 and 1-33](#)), which are not found in the upper airway of the mouse lung (see [Fig. 1-33](#)). Thus different cell types contribute to airway secretions in the two species.

Lastly, the lung's developmental stage at full term is different between mice and humans. In mice, lung development at full term is at the saccular stage. In humans, lung development at full term is at the beginning of the alveolar stage. This timing difference is helpful to keep in mind when developmental comparisons are made (see also Chapter 2).

In general, those who use animal models should recognize that, even in the normal setting, important differences in the structure, cellular composition, and development may affect the applicability of findings to the human lung.

Table 1-3 Comparative Anatomy of Mouse and Human Lungs

Anatomic Feature of the Lung	Mouse	Human
Visceral pleura thickness	5-20 μm	25-100 μm
Visceral pleura arterial supply	Pulmonary	Systemic (bronchial)
Lobes	4 right; 1 left	3 right; 2 left
Airway generations	13-17	17-21
Airway branching pattern	Single	Dichotomous
Main bronchus diameter	$\approx 1\text{ mm}$	$\approx 10\text{-}15\text{ mm}$
Intrapulmonary airway cartilage	No	Yes
Tracheal epithelium thickness	11-14 μm	50-100 μm
Tracheal club cells (Clara)	$\approx 50\%$	None
Tracheal goblet cells	Absent	Present
Tracheal submucosal glands	Absent	Present
Proximal intrapulmonary airway thickness	8-17 μm	40-50 μm
Proximal intrapulmonary airway club cells	$\approx 60\%$	None
Proximal intrapulmonary airway goblet cells	Absent	Present
Proximal intrapulmonary airway submucosal glands	Absent	Present
Terminal bronchiole diameter	$\approx 10\text{ }\mu\text{m}$	$\approx 600\text{ }\mu\text{m}$
Terminal bronchiole thickness	$\approx 8\text{ }\mu\text{m}$	Not determined
Terminal bronchiole club cells	$\approx 70\%$	None
Respiratory bronchioles	Absent (or one)	Present ($\approx 150,000$)
Lung parenchyma-total lung volume ratio	$\approx 18\%$	$\approx 12\%$
Alveolar diameter	30-80 μm	100-200 μm
Air-blood barrier thickness	$\approx 0.32\text{ }\mu\text{m}$	$\approx 0.68\text{ }\mu\text{m}$
Pulmonary venule location	Next to bronchioles	Along interlobular septa
Developmental stage at full term	Saccular	Alveolar

Adapted from [references 235–237](#).

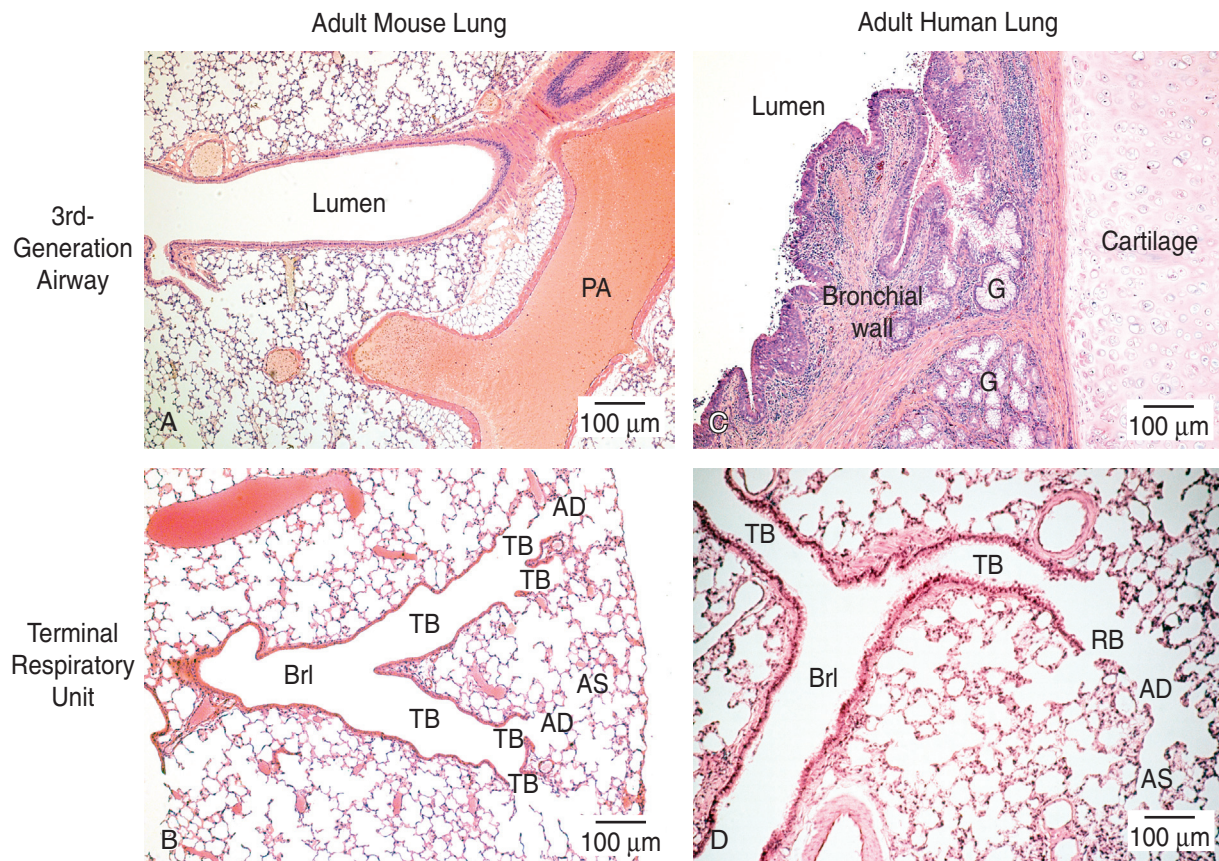

Figure 1-33 Comparison of lung morphologic features between adult mice (left column) and humans (right column). The four panels are the same magnification, as shown by the scale bar in each panel. The upper row compares 3rd-generation, intrapulmonary airways between mouse (A) and human (C). The mouse's airway lumen is narrower than the same-generation airway (bronchus) in the human. Absent from the wall of the mouse's airway wall are cartilage and submucosal glands (G), both of which are obvious in the wall of the bronchus of the human airway. The lower row compares terminal respiratory units between mouse (B) and human (D). The mouse's terminal respiratory units do not have respiratory bronchioles; therefore terminal bronchioles (TB) open directly into alveolar ducts (AD). By comparison, the human's terminal respiratory units have respiratory bronchioles (RB), which open into alveolar ducts (AD) and air space (AS). Brl, bronchiole; PA, pulmonary artery. (Mouse and human lung tissue, 5- μm -thick paraffin-embedded sections, light microscopy.)

Key Points

- The primary function of the lung is ventilation-perfusion matching for efficient gas exchange between alveolar air and alveolar capillary blood.
- The anatomic arrangements of the pulmonary arteries beside the airways are a reminder of the relationship between perfusion and ventilation that determines the efficiency of normal lung function.
- The major physical problem of gas exchange is the slowness of oxygen diffusion through water. Thus the alveolar walls must be extremely thin. Because of that thinness, the thickness of the red blood cell forms a substantial portion of the air-blood diffusion pathway.
- The airways form the connection between the outside world and the terminal respiratory units; therefore the airways are of central importance to our understanding of lung function in health and disease.
- The terminal respiratory unit consists of all the alveolar ducts, together with their accompanying alveoli, that stem from the most proximal (first) respiratory bronchiole, and contains approximately 100 alveolar ducts and 2000 alveoli. The functional definition of the terminal respiratory unit is that, because gas-phase diffusion is so rapid, the partial pressures of oxygen and carbon dioxide are uniform throughout the unit.
- Smooth muscle cells form circular bands around the airway epithelium as far peripherally as the respiratory bronchioles. Tone in the smooth muscle is altered by the autonomic nervous system and by mediators released from mast cells, inflammatory cells, and neuroendocrine cells.
- Because smooth muscle is in the pulmonary vessels on both the arterial and the venous side down to precapillary and postcapillary vessels, any segment can contribute to active vasomotion and therefore pulmonary vascular resistance.
- Normally, capillary blood volume is equal to or greater than stroke volume. Thus, under normal resting conditions, the volume of blood in the pulmonary capillaries is well below its maximal capacity. Recruitment can increase capillary blood volume threefold.
- The endothelial cells of the pulmonary circulation manifest a remarkable number of metabolic activities.
- The type II cell is the major synthesizing and secreting factory of the alveolar epithelium and implements epithelial repair via its ability to proliferate.
- The clearance of particulate matter impinging on the alveolar surfaces is dependent on the slow turnover and movement of the alveolar surface liquid, as well as on the phagocytic function of the macrophages and the clearance function of the pulmonary lymphatics.

ACKNOWLEDGMENTS

This chapter is dedicated to the memory of Norman C. Staub, MD, who was my teacher, mentor, colleague, and friend. Special appreciation is extended to Dr. Kenneth “Bo” Foreman, Associate Professor of Physical Therapy, College of Health, University of Utah, for videography expertise to create the online supplemental digital videos of lung movements. Portions of this work were supported by grants from the National Institutes of Health (HL038075, S10-RR004910, S10-RR010489, HL049098, SCOR Grant HL050153, HL062875, and HL110002).

INTRODUCTION

Multicellular life requires the use of oxygen for the generation of high-energy compounds (e.g., adenosine triphosphate) to sustain the metabolic activities of complex organisms. Because multicellular organisms depend on oxygen, they have evolved systems for its efficient acquisition and distribution. A benchmark in the adaptation of vertebrates living on land was the development of a gas exchange system that provided a sufficient amount of oxygen to meet the metabolic requirements of cellular respiration. As organisms increased in size, the surface area required for adequate gas exchange became significantly larger; for example, the surface area of the adult human lung epithelium has been estimated to be 70 m².¹ The problem of generating such a large surface area in a confined space has been solved in the basic structure of the lung, where branched epithelial tubules conduct air to millions of alveoli that lie closely apposed to the lung microvasculature. The epithelium lining the surface of the lung is continuously exposed to biologic and chemical hazards from the environment, which has also necessitated the development of an innate defense system in the lung. Early embryologic experiments established that lung morphogenesis is critically dependent on reciprocal interactions between the lung endoderm and its surrounding splanchnic mesoderm, which supplies progenitors of endothelial cells, smooth muscle cells, mesothelial cells, and fibroblasts. As we will discuss, these interactions are complex and highly regulated in time and space. Disruptions in the lung developmental program, be it for genetic or epigenetic reasons, can lead to compromised structure and function. A better understanding of the molecular mechanisms controlling lung development will optimize therapeutic strategies to treat the diseased or malformed lung. Several additional recent reviews are also available.²⁻⁶

STAGES OF LUNG DEVELOPMENT

Lung development has traditionally been divided into five stages that are primarily based on histologic appearance (Fig. 2-1). After lung bud formation the basic branching pattern of the pulmonary tree and an associated vascular plexus is established during the **embryonic** and **pseudo-**

glandular stages. The epithelial branching program, which is under genetic control, is stereotyped and uses three geometrically distinct local modes of branching that proceed in three different sequences.⁷ Human lung development begins with the emergence of the laryngotracheal groove from the floor of the foregut endoderm during the fourth week of gestation. A few days later the caudal end of the primordium enlarges and bifurcates, giving rise to the left and right bronchial buds (see Fig. 2-1A). These buds elongate caudally during the fifth week of gestation, when a second round of branching takes place, resulting in three secondary buds in the right lung and two in the left. These buds will become the primary lobes of the left and right lung. A third round of branching gives rise to bronchial tubules that will become the bronchopulmonary segments in the mature lung. Concurrent with these events in the distal region, the cranial portion of the primordium gives rise to the trachea and larynx, which separate from the esophagus by the end of this stage. The lung epithelium at this stage is tall columnar and shows no morphologic evidence of differentiation. At the molecular level, however, some aspects of epithelial differentiation have already begun; for example, the most distal epithelial cells express messenger RNA for the lung-specific marker *surfactant protein (SP) C*.⁸ The lung mesenchyme, which is derived from splanchnic mesoderm, is loosely organized at the beginning of this stage and appears to lack vascular structures. In situ hybridization studies probing for the *vascular endothelial growth factor (VEGF)* receptor FLK1 have demonstrated, however, that vascular precursors are closely apposed to the distal epithelium at the time of bud induction.⁹ These cells form a vascular plexus (see Fig. 2-1B) by a process termed “vasculogenesis,” wherein vessels are formed de novo by the organization of vascular precursors. By the end of the embryonic stage, pulmonary arteries and veins connect this plexus to the atria; the pulmonary arteries and veins grow into the lung by angiogenesis, with new branches arising from preexisting vessels.

Dichotomous and lateral branching of the lung epithelium continues during the **pseudoglandular** stage, which lasts from week 5 to week 17 of gestation. This results in the final pattern of the pulmonary tree, which comprises 22 to 23 generations of bronchial tubules. Terminal bronchioles branch distally to give rise to the acinar tubules and buds that will eventually form pulmonary acini in the adult

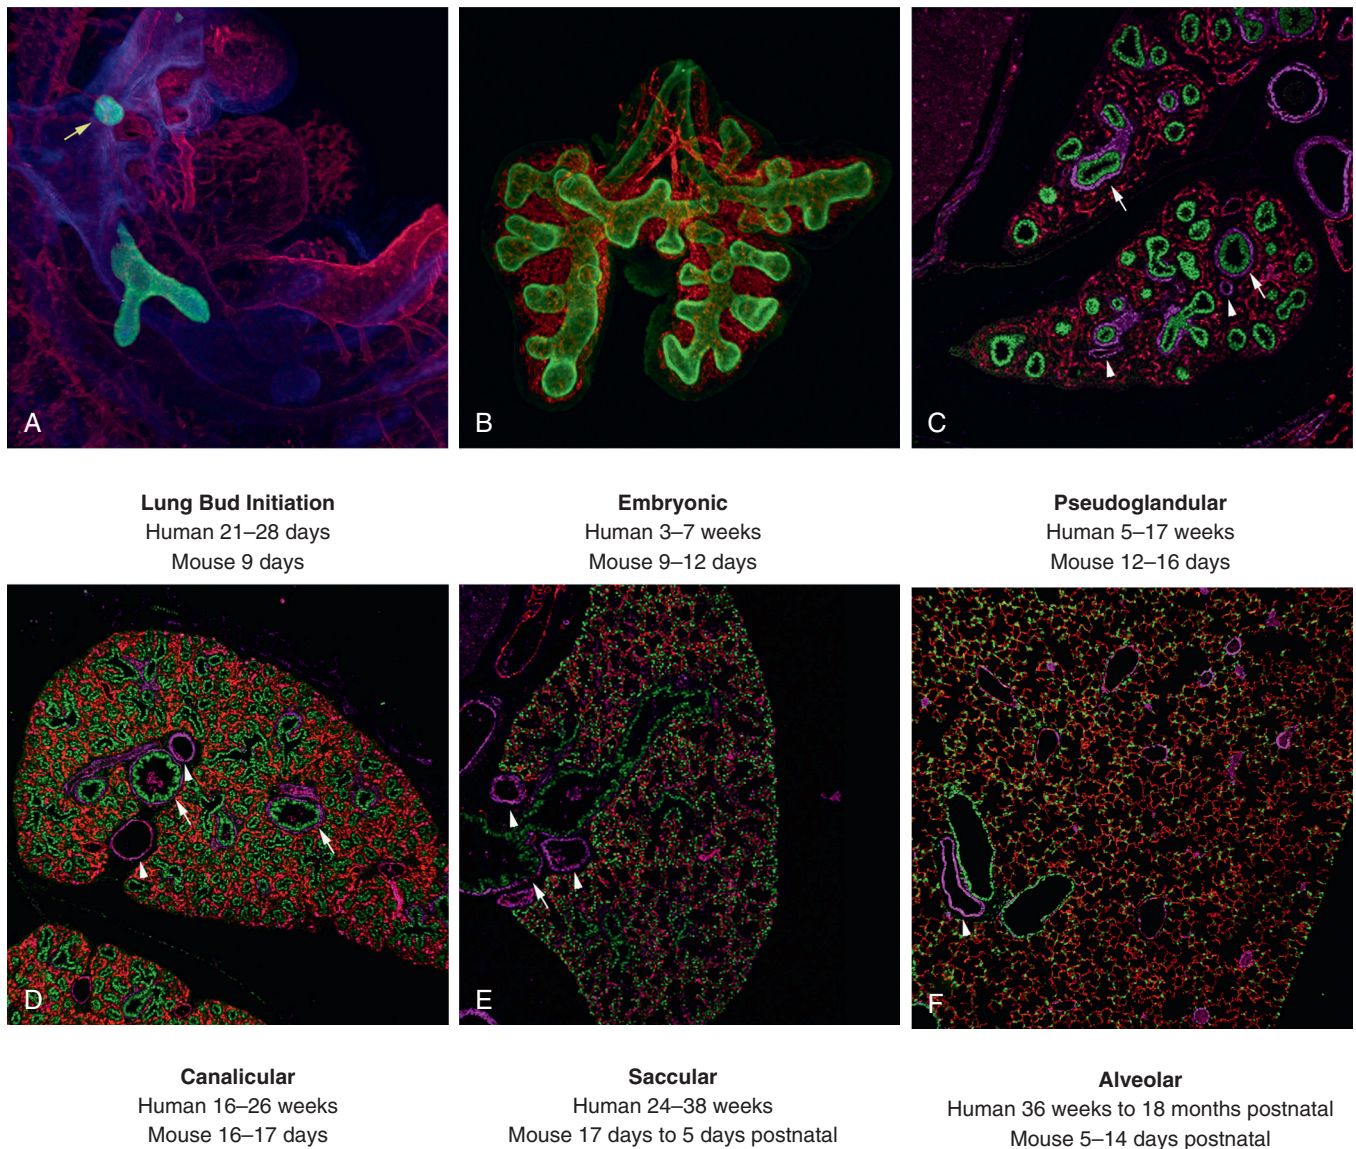

Figure 2-1 Morphology of the stages of lung development. Mouse lungs from the indicated developmental stages were stained with an antibody against Nkx2-1 to identify epithelial cells in the respiratory lineage (*green*), an antibody against endomucin to identify vascular cells (*red*), and an antibody against α -smooth muscle actin to identify smooth muscle cells (*magenta*). An antibody against E-cadherin identifies the foregut endodermal epithelium (*blue*) (**A**). All images of sectioned lungs (**C–F**) are at the same magnification. **A**, Lung buds originate as a pair of outpocketings from the ventral foregut endoderm on day E9.5 in the mouse; the lung endoderm stains positive for Nkx2-1, as does the primitive thyroid rudiment (*yellow arrow*). **B**, During the embryonic stage, dichotomous and lateral branching of the lung epithelium continues. Vascular precursors are already present and form a plexus surrounding the epithelium. **C**, During the pseudoglandular stage, the lung primarily consists of epithelial tubules surrounded by a relatively thick mesenchyme. Proximal epithelial cells show tall columnar morphologic characteristics, whereas more distal epithelial cells are cuboidal. The vasculature branches in parallel with the epithelium, and smooth muscle cells surrounding airways (*white arrows in all panels*) and vessels (*white arrowheads in all panels*) are evident. **D**, During the canicular stage, epithelial acini appear, and the vasculature becomes more abundant and closely apposed to the epithelium. **E**, During the saccular stage, type I cell differentiation increases air space size. The vasculature has continued to expand, fully investing the lung parenchyma. Fusion of the epithelial and endothelial basal laminae brings capillaries and type I epithelial cells into close association. **F**, During the alveolar stage, the formation, lengthening, and thinning of secondary septa markedly increase the epithelial surface area. The capillaries, which until now have existed as a double septal network, have fused into one. (Confocal images generated by Jamie Havrilak, Graduate Program in Molecular and Developmental Biology, Cincinnati Children's Hospital Medical Center.)

(see Fig. 2-1C). Morphologic differences in the epithelium are apparent. The proximal epithelium is initially populated by relatively undifferentiated columnar, glycogen-rich cells, but ciliated, nonciliated, goblet, mucous, basal, and neuroendocrine cells are identifiable by the end of this stage. The distal epithelium is populated by distal epithelial

cells, the precursors of alveolar type II cells, which are cuboidal columnar and contain copious amounts of glycogen. Smooth muscle cells differentiate in the mesenchyme and surround the epithelium perpendicular to the long axis of the tubules; this proceeds in a proximal-to-distal manner. The pulmonary vasculature branches in parallel with the

airway epithelium (see Fig. 2-1C), and pulmonary lymphatics initiate as buds from the veins.¹⁰

Patterning of the pulmonary tree is completed at the beginning of the **canalicular** stage (16 weeks to 26 weeks; see Fig. 2-1D), and the cells constituting the proximal epithelium continue to differentiate as ciliated, nonciliated, and secretory cells. Among the latter are club cells (Clara), identifiable by the presence of the cell-specific *club cell secretory protein* (Clara) (CCSP). Acinar tubules and buds, which are lined by cuboidal epithelial cells, expand and differentiate to form pulmonary acini consisting of respiratory bronchioles, alveolar ducts, and alveoli. Nascent type II cells containing increasing amounts of surfactant-associated proteins and phospholipids become prominent in the distal epithelium. Differentiation of squamous type I cells from type II cells begins. A dramatic expansion of the pulmonary capillary bed (vascular canals) in the lung parenchyma gives this stage its name (see Fig. 2-1D). These vessels surround the developing acini and come in direct contact with the epithelium, giving rise to the primordial air-blood barrier.

During the **saccular** stage, which persists from week 24 until term, the terminal acinar tubules in the lung periphery continue to branch and air space size increases. Alveolar type II cells undergo significant maturation, as evidenced by increased synthesis of SP-A, SP-B, SP-C,¹¹ and SP-D¹² and of surfactant phospholipids.¹³ Glycogen stores, which serve as a substrate for phospholipid synthesis,¹⁴ decrease, while the number of lamellar bodies increases. Squamous type I cells continue to differentiate and constitute an increased proportion of the distal lung surface, thereby increasing the effective area for gas exchange (see Fig. 2-1E). Septal walls consist of a central connective tissue core with a capillary network on each side. Subsequent fusion of the basal laminae of the distal epithelium and endothelium brings capillaries into close association with type I cells, which decreases the diffusion distance between air spaces and capillaries to allow more efficient gas exchange (see Fig. 2-1E).

The transition from the canalicular to saccular stage of lung development marks the threshold of viability for preterm infants who have access to neonatal intensive care support.^{15,16} Before 22 weeks' gestation there is insufficient surface area in the distal pulmonary tree to support safe, reliable oxygenation and ventilation, even when surfactant replacement therapy and sophisticated mechanical ventilation techniques are available. Survival at 23 weeks' gestation ranges from 15% to 30%. Mortality decreases with each additional week of gestation; by 25 weeks, survival exceeds 60%, although significant morbidity in the form of *bronchopulmonary dysplasia* (BPD) and neurodevelopmental compromise persists.¹⁷

As the threshold of viability is crossed, *respiratory distress syndrome* (RDS) becomes the primary source of morbidity and mortality for the preterm infant. RDS is a consequence of deficient surfactant production, leading to terminal airway atelectasis and epithelial injury. The subsequent capillary leak produces the hyaline membranes that are classically associated with this disease. Surfactant replacement therapy has dramatically improved RDS survival rates and reduced morbidity. Term infants affected by RDS

often have comorbid conditions such as maternal diabetes, which delay maturation of the surfactant production system.

Genetic mutations leading to SP-B deficiency result in a clinical presentation indistinguishable from the early stages of RDS. Affected infants, however, are typically full term and have only a transient response to surfactant replacement therapy, which leads to early neonatal death or the development of severe neonatal chronic lung disease. The only definitive treatment is lung transplantation. Lethal respiratory failure in a mouse model of SP-B deficiency can be reversed with targeted expression of an SP-B transgene, demonstrating the potential for gene therapy.¹⁸ Mutations of SPC produce a spectrum of pulmonary disorders during infancy, including interstitial pulmonary fibrosis.¹⁹ As with SP-B deficiency, surfactant replacement therapy has little or no benefit, with lung transplantation as the only documented potential cure. Other genetic defects of the surfactant production system also lead to fatal surfactant deficiency in the neonate. Infants deficient in ABCA3, which transports surfactant phospholipids to lamellar bodies, have normal SP-B expression but develop unexplained lethal respiratory failure and death within 1 month of birth.²⁰

The final stage of lung development is the **alveolar** stage, which lasts from week 36 of gestation through the first 18 months of postnatal life. As the name implies, true alveoli are generated from terminal saccules during this stage. Interstitial tissue in primary septa is reduced, while secondary septa markedly lengthen and thin (see Fig. 2-1F). Concomitant with these changes is the fusion of the double septal capillary network into one (see Fig. 2-1F). This remodeling requires an initial burst of interstitial fibroblast proliferation, which subsequently slows down, and the cells synthesize increased amounts of collagen and elastin. Septation results in a marked increase in the number of alveoli from approximately 30 million at term to 300 million in the adult. Increased numbers of type II and type I cells accompany alveolar expansion, with type I cells now covering 95% of the alveolar surface area.²¹

BPD, which is typically restricted to infants born before 32 weeks' gestation, represents a particularly challenging complication.^{21a} The condition is only associated with preterm birth and is defined by a characteristic appearance on chest radiograph and persistent requirement for supplemental oxygen beyond 36 weeks after conception.²² In the era of surfactant replacement therapy, BPD is distinguished by alveolar simplification due to the apparent arrest of the alveolarization during the third trimester.²³ Compromised oxygenation and ventilation may worsen as infant somatic growth progresses and attendant metabolic demands outstrip pulmonary function. Respiratory morbidity is not restricted to infants born before 32 weeks' gestation. Late-preterm infants born between 32 and 37 weeks' gestation are more likely than term infants to require respiratory support, including positive-pressure ventilation, after birth.²⁴ Given the dramatic increase in alveolar number during the late third trimester, it follows that late-preterm infants may have a smaller margin of safety when making the transition to extrauterine life.

Figure 2-2 Histopathologic features of human alveolar capillary dysplasia and extralobar pulmonary sequestration. **A**, Section of normal infant lung stained with hematoxylin and eosin demonstrates a typical bronchovascular bundle incorporating a small bronchus (Br) and artery (A), without an accompanying vein. A typical alveolar network with abundant air spaces (asterisk) is present. **B**, Pentachrome-stained section from a full-term newborn with alveolar capillary dysplasia. There is abundant mesenchyme separating rudimentary, dysplastic terminal air spaces (asterisk). Alveolar capillaries (arrow) are sparse in number and distended. There is misalignment of the pulmonary vasculature. A pulmonary artery (A) and prominent muscularis and bronchus (Br) are accompanied by an anomalous pulmonary vein (V). The paucity of alveolar capillary structures accounts for the profound pulmonary hypertension in these patients. (x10 original magnification.) **C**, Immunohistochemistry of extralobar pulmonary sequestration from a full-term neonate demonstrates expression of pro-surfactant protein C in the epithelium (brown-staining cells). The sequestration has the histologic appearance of primitive lung at the canalicular stage of development with an abundance of mesenchyme separating nascent air space structures (arrow). (Micrographs courtesy of Dr. Susan Wert, Division of Pulmonary Biology, Cincinnati Children's Hospital Medical Center, and Dr. Gail Deutsch, Division of Pathology, Seattle Children's Hospital.)

TISSUE INTERACTIONS AND LUNG DEVELOPMENT

A basic tenet of lung development is that it requires inductive interactions between the endodermal epithelium and the mesodermal mesenchyme. Reciprocal inductive interactions involve one cell type signaling to another cell type and then responding to signals sent back; both cell types are thus signaling and responding to each other. This is particularly evident in the embryonic and pseudoglandular stages, where it has been shown conclusively that lung epithelium must be associated with lung mesenchyme in order to survive²⁵ and branch.²⁶ The factors that drive branching morphogenesis are diffusible, because embryonic lung epithelium branches when separated from lung mesenchyme by a filter that prevents direct cell-cell contact but allows diffusion of soluble factors.²⁷ Importantly, these experiments also showed that survival of lung mesenchyme is dependent on the presence of lung epithelium, underscoring that induction is reciprocal. The fate of the entire respiratory endoderm, from the trachea to the bud tips, however, is not fully committed during the embryonic stage. Reciprocal recombination experiments have shown that distal lung mesoderm can reprogram tracheal endoderm to branch and differentiate like lung,^{28,29} and that tracheal mesoderm can reprogram lung endoderm to differentiate like trachea.^{30,31}

Bronchopulmonary sequestration may represent an intriguing manifestation of aberrant pulmonary endoderm-mesoderm interaction. These masses of abnormal lung tissue, which may be contained within the lung or in an extrapulmonary location within the abdomen, may be in direct communication with gastrointestinal tract structures, suggesting ectopic induction of embryonic foregut. The histopathologic appearance of these lesions includes typical cellular components of pulmonary parenchyma along with inflammatory and fibrotic components (Fig. 2-2C).³²

Normal lung function requires the precise alignment of the distal epithelium and the vasculature to meet the

respiratory requirements of the developing organism. Certain lethal congenital malformations of the lung, such as *alveolar capillary dysplasia with misalignment of pulmonary veins* (ACD/MPV), are due to a perturbation in the relationship between vascular and airway development. ACD/MPV is characterized by a paucity of alveolar capillaries, thickened pulmonary mesenchyme, and misalignment of the pulmonary veins, which reflect the reciprocal relationship required for airway and vascular development (see Fig. 2-2B). ACD/MPV is associated with mutations in the transcription factor *FOXF1*, which is expressed in the lung mesenchyme.³³ The alveolar simplification of BPD is also accompanied by a relative paucity of alveolar capillaries that is reminiscent of ACD/MPV. Evidence that *vascular endothelial growth factor A* (VEGF-A), which is produced by lung epithelial cells, can reverse the alveolar defect further reinforces the concept of interdependent development of vascular and airway structures.³⁴

MOLECULAR REGULATION OF LUNG DEVELOPMENT

Elucidation of the factors that regulate lung growth and development has been the focus of an intense research effort.^{34a} This stems not only from a desire to understand the basis of pulmonary pathologic conditions present at birth, but also from the possibility that understanding how the lung develops will provide insight into how the lung repairs itself following injury or disease. Given the morphogenetic precision required to generate a lung that can function effectively in gas exchange, coupled with the fact that the lung contains over 40 differentiated cell types,¹ it is not surprising that the molecular regulation of lung development is proving to be very complex. Identifying the factors involved provides only part of the story. When, where, how much of, and for how long these factors are expressed must also be considered. The fact that there is crosstalk between some of the identified pathways significantly increases the level of complexity.

DIFFUSIBLE MEDIATORS OF LUNG DEVELOPMENT

Fibroblast Growth Factors and Fibroblast Growth Factor Receptors

In both humans and mice, the *fibroblast growth factor* (FGF) family comprises 22 structurally related molecules³⁵; among these, FGF1, 2, 7, 9, 10, and 18 have been localized to the developing lung. FGFs bind and signal through high-affinity, ligand-dependent transmembrane receptors (*fibroblast growth factor receptors* [FGFRs]) that contain an intracellular tyrosine kinase domain. There are four FGFRs, all of which are expressed in the lung. Alternative messenger RNA splicing results in two isoforms each for FGFR1, FGFR2, and FGFR3 that have distinct ligand specificities.³⁶ FGFR activation is modulated by heparin or heparan sulfate.³⁷

FGF1 and *FGF2* are not critical for lung development, because the single deletion of either gene or the double

ablation of both has no effect on lung development. FGF10 is an ideal candidate for mediating tissue interactions in the lung, because it is expressed in the mesenchyme, whereas its primary receptor, FGFR2b, is expressed by epithelial cells. Ablation of either *FGF10*³⁸ or *FGFR2b*³⁹ results in complete pulmonary agenesis caudal to the trachea. The basis for this phenotype comes from the ability of FGF10 to induce lung epithelial budding by chemoattraction^{40,41}; in the absence of FGF10, primary buds cannot form. FGF10 affects the expression of many target genes in early lung epithelium,⁴² including other important signaling molecules such as *bone morphogenetic protein 4* (BMP4)⁴⁰ and Notch family members.⁴³

Like FGF10, FGF9 acts as a mediator of reciprocal tissue interactions, because it is expressed in the epithelium and mesothelium, whereas its receptor (FGFR2c) is found in the mesenchyme. FGF9 controls lung mesenchyme size by regulating cell proliferation.⁴⁴ The observation that the amount of available mesenchyme appears to control lung branching²⁵ is consistent with the finding that the lungs of *Fgf9*-null mice are severely hypoplastic, with decreased amounts of mesenchyme and reduced *Fgf10* expression.⁴⁵ The observation that *Fgf18*-null mice exhibit reduced alveolar size resulting from reduced cell proliferation during the saccular stage⁴⁶ suggests a role for FGF18 in late lung development. FGF7 has been shown to stimulate lung epithelial cell proliferation,⁴⁷ as well as surfactant protein gene expression and surfactant phospholipid synthesis in type II cells.^{48,49} Transgenic overexpression of *Fgf7* in the developing mouse lung epithelium results in lesions resembling congenital cystic adenomatoid malformations⁵⁰; examination of human congenital cystic adenomatoid malformations, however, shows that FGF7 expression is actually decreased and FGF10 expression is unchanged.⁵¹ Although intraperitoneal injection of neutralizing antibodies against *Fgf7* inhibits postnatal lung growth and alveolus formation,⁵² mice with a targeted deletion of *Fgf7* have no apparent lung phenotype.⁵³ Other FGFs are also required during alveologenesis, because mice with deletions of both *Fgfr3* and *Fgfr4* fail to form normal alveoli.⁵⁴

The Sprouty (SPRY) proteins, which antagonize FGFR signaling, modulate the effects of FGFs in the developing lung. Although single deletion of either *Spry2* or *Spry4* has no effect on lung development, mice null for both genes have defects in multiple organs, including the lung.⁵⁵

Retinoic Acid

Retinoic acid (RA), the active derivative of vitamin A, is essential for the normal development of many tissues, including the lung. Maternal vitamin A deficiency results in severe respiratory phenotypes in offspring, including tracheoesophageal fistula, lung hypoplasia, and lung agenesis.⁵⁶ RA signals through RAR and RXR nuclear receptors, both of which have α , β , and γ isoforms, and these are expressed in the lung from the outset of development. Mice with double deletions of *Rara/Rarb* or *Rara/Rarb* show the same lung abnormalities as those seen in vitamin A-deficient embryos.⁵⁷ The mechanism by which RA controls lung morphogenesis is not fully resolved. Data from cultured early embryonic foreguts suggest that RA allows activation of *Wingless* (Wnt) signaling by inhibiting *Dickkopf1* (DKK1); this affects FGF10 expression in the mesoderm, as

well as maintenance of lung progenitor cell fate.⁵⁸ RA further affects lung bud induction by inhibiting *transforming growth factor-β* (TGF-β) activity in the prospective lung field, which in turn allows expression of FGF10.⁵⁹

RA also enhances perinatal alveolus formation in rodents,⁶⁰ which has led to its clinical use for the prevention of BPD.⁶¹ The effect is modest but significant; about 15 infants must be treated to prevent one case of BPD.⁶² The mechanism is not understood in detail but is likely related to maintenance of alveolarization after preterm delivery, reducing the potential for alveolar simplification.

Sonic Hedgehog

The hedgehog signaling pathway plays an important role in the development of multiple organs.⁶³ *Sonic hedgehog* (SHH) is highly expressed in the developing lung epithelium,⁶⁴ and its primary receptor, *patched 1* (PTCH1), is found in mesenchymal cells,⁶⁵ suggesting that SHH is part of an epithelial-mesenchymal inductive loop. Shh is initially expressed throughout the epithelium but becomes restricted to subsets of cells from day E16.5 onward.⁶⁶ *Shh*-null mice form lungs, indicating that Shh is not required for lung specification and bud induction; however, these lungs are severely hypoplastic,⁶⁷ suggesting that Shh is involved in regulating branching morphogenesis. *Shh* deletion profoundly affects lung growth and patterning, but the specification of epithelial cell types appears to be unaffected.⁶⁸ Because Shh serves as a survival factor for lung mesenchymal cells,⁶⁹ the lung hypoplasia seen in *Shh*-null embryos may be due to a decrease in mesenchymal mass. Shh is also a negative regulator of Fgf10, and *Shh*-null embryos exhibit expanded Fgf10 expression.⁶⁸ A clinical syndrome with a respiratory phenotype that is consistent with disruption of SHH signaling is Smith-Lemli-Opitz.⁷⁰ Smith-Lemli-Opitz syndrome is phenocopied by mutations in Δ -7-dehydrocholesterol reductase (*DHCR7*), which is involved in cholesterol synthesis⁷¹; cholesterol modification of SHH is required for effective signaling.^{72,73}

SHH levels are modulated by its binding to PTCH1.⁷³ In the absence of ligand, PTCH1 represses *Smoothed* (SMO) and prevents activation of the hedgehog signaling pathway. SHH also up-regulates PTCH1 expression, and any PTCH1 in excess of that involved in controlling signaling binds SHH and sequesters it, creating a negative feedback loop that restricts its spread. Another molecule regulating SHH levels is *hedgehog interacting protein* (HHIP), a membrane-bound protein that binds all mammalian hedgehog proteins and, like PTCH1, is up-regulated in response to SHH.⁷⁴ Targeted deletion of *HHIP* results in lung hypoplasia⁷⁵ that may be due to a loss of FGF10 expression at the prospective sites of bud formation as a result of increased SHH signaling.

Transforming Growth Factor-β Superfamily

The TGF-β superfamily comprises activins, inhibins, the BMPs, müllerian inhibiting substance, and TGF-β1, 2, and 3. TGF-β1 treatment of cultured embryonic lung explants⁷⁶ or misexpression of TGF-β1 targeted to the lung *in vivo*⁷⁷ severely inhibits branching morphogenesis. This is likely due to the ability of TGF-β1 to inhibit FGF10 expression.⁵⁹ TGF-β1 signals through a heteromeric complex of type I (TGF-βRI) and type II (TGF-βRII) receptors and exerts its effects on downstream target genes via the Smad family of

proteins.⁷⁸ Inhibition of TGF-βRII in cultured embryonic lungs increases lung branching,⁷⁹ as does attenuation of SMAD2/3,⁸⁰ underscoring the inhibitory nature of TGF-β1 on lung morphogenesis. *Tgfb1*-null mice show no apparent lung phenotype, although it should be noted that 50% of these mice die on E10.5, just after the onset of lung development.⁸¹ Most *Tgfb2*-null mice die shortly before or during birth with a wide range of developmental defects. The lungs of neonates have dilated conducting airways and collapsed terminal and respiratory bronchioles.⁸² Deletion of *Tgfb3* results in retarded development and differentiation of the lung epithelium, mesenchyme, and vasculature.⁸³ The fact that TGF-β3 appears to promote morphogenesis contrasts with the inhibitory function of TGF-β1, suggesting that these ligands affect distinct aspects of lung development.

Of the four BMPs expressed in the developing lung (BMP3, 4, 5, and 7), BMP4 has been the focus of the most studies. *Bmp4* is expressed in the ventral foregut mesenchyme before lung bud induction and then is expressed in the distal epithelium and proximal mesenchyme after the lung has formed. In the mouse, epithelial expression declines in the distal epithelium before birth but begins in the capillary endothelium. *Bmp4* expression is up-regulated by Fgfs in the epithelium and by Shh in the mesenchyme. Specific deletion of *Bmp4* or *BMP receptor 1a* (*Bmpr1a*) from the distal lung epithelium results in reduced proliferation, increased apoptosis, and cystic morphogenesis.⁸⁴ Early endodermal deletion of both *Bmpr1a* and *Bmpr1b* results in reduced ventral *Nkx2.1* expression, which is replaced by expanded expression of dorsal *Sox2*.⁸⁵ These data support a model in which BMP4 promotes the proliferation and survival of undifferentiated lung progenitor cells.

Wnts and β-Catenin

Members of the Wnt family of secreted glycoproteins are critically involved in cell fate determination, proliferation, survival, and motility in organogenesis.⁸⁶ Wnt ligands bind their receptors to activate a pathway that ultimately stabilizes β-catenin, which then interacts with nuclear *T-cell factor/lymphoid enhancer factor* (TCF-LEF) transcription factors to modulate transcription of downstream target genes.⁸⁷ Wnts1, 2, 2b, 5a, 7b, and 11 are expressed in the lung. Their secretion is mediated by the transmembrane protein *Wntless* (WLS); deletion of WLS from the lung endoderm disrupts branching morphogenesis and pulmonary endothelial differentiation.⁸⁸ Canonical Wnt signaling plays a critical role in lung development, because endodermal deletion of β-catenin abrogates specification of lung progenitors and leads to complete lung agenesis.⁸⁹ The ligands responsible for lung progenitor specification are likely Wnt2/2b, because their dual deletion phenocopies exactly the endodermal loss of β-catenin.⁹⁰ Proximal-distal airway patterning and epithelial cell differentiation are disrupted when Wnt signaling is inhibited after specification of lung progenitors, either by targeted epithelial deletion of β-catenin⁹¹ or by misexpression of the Wnt antagonist *Dkk1*.⁹² In addition to its role in specifying lung endoderm, Wnt2 also activates a signaling network necessary for smooth muscle differentiation.⁹³ Inactivation of Wnt5a results in a foreshortened trachea, distended distal airways, and retarded lung maturation.⁹⁴ Mice null for *Wnt7b* die at birth from respiratory failure. Early proliferation is reduced

in both epithelial and mesenchymal tissue compartments, leading to lung hypoplasia, although cell fate specification and overall tissue architecture are unchanged.⁹⁵ Constitutive activation of Wnt signaling in the developing lung epithelium with hyperactive β -catenin results in lungs that lack fully differentiated cell types and instead contain multiple intestinal and nonlung secretory cell types.⁹⁶ Taken together, these observations indicate that the temporospatial regulation of Wnt signaling must be tightly regulated to ensure normal lung morphogenesis and differentiation.

Platelet-Derived Growth Factor

The *platelet-derived growth factor* (PDGF) family consists of five different disulphide-linked dimers built up of four different polypeptide chains encoded by four different genes. PDGF-A, which homodimerizes with itself or heterodimerizes with PDGF-B, plays an important role in lung development. PDGF-A is expressed in distal lung epithelium, whereas its receptor, PDGFRA, is expressed in nearby mesenchymal cells, indicative of a paracrine signaling loop between the epithelium and mesenchyme. Deletion of *PDGF-A* results in arrested alveolus formation and postnatal death.⁹⁷ The lungs lack the differentiated alveolar myofibroblasts that produce elastin, which is critical for alveolus formation.

Vascular Endothelial Growth Factor

VEGF-A, C, and D are all found in the lung. The temporal and spatial expression of VEGF-A during lung development implies a central role in the maturation and organization of the pulmonary vascular network. VEGF-A is expressed in epithelial and mesenchymal compartments during the embryonic and pseudoglandular stages, becoming more restricted to the epithelium as development progresses into the canalicular stage.^{9,98} VEGF-A exists as three isoforms (120, 164, and 188) that have distinct functions in vascular development.⁹⁹ Genetic studies in mice demonstrate the importance of local tissue concentrations of Vegf-a to effect appropriate vascular development and distal airway structures. Increased expression of Vegf164 in distal epithelium disrupts assembly of the vascular plexus and arrests airway branching without affecting endothelial cell proliferation or survival, indicating that crosstalk between the developing epithelium and vasculature is required for normal morphogenesis.¹⁰⁰ Vascular ablation in the early lung causes significant alterations in stereotypic branching of the epithelium.¹⁰¹ VEGF-A expression is controlled by multiple mediators, such as FGFs and SHH.¹⁰²

Glucocorticoids

Glucocorticoids exert potent effects on a variety of different tissues, with a common theme that they induce the precocious appearance of normal developmental events. The effects of glucocorticoids on lung function have been a topic of intense interest since the observation that dexamethasone accelerates lung maturation in premature lambs.¹⁰³ Glucocorticoid receptors are present on the developing pulmonary epithelium as airway branching progresses during the pseudoglandular stage of lung development. Epithelial expression persists through the saccular and alveolar stages, accompanied by the onset of expression within the mesenchymal compartment.¹⁰⁴ Exogenous glucocorticoids stimulate morphologic maturation and many aspects of

surfactant phospholipid biosynthesis.¹⁰⁵ Targeted disruption of the glucocorticoid receptor in mice leads to respiratory distress and early neonatal death¹⁰⁶; the lungs of these animals are atelectatic with blunted alveolarization. Although the number of type II cells is increased by 30%, the relative expression of Sp-a and Sp-c is decreased by 50%. The number of type I cells is decreased by 50%, as are the type I cell markers T1 α and aquaporin-5, suggesting that glucocorticoids facilitate the differentiation of type II cells into type I cells.¹⁰⁷ Somewhat paradoxically, however, mice null for corticotropin-releasing hormone show deficits in septal thinning, air space formation, and content of Sp-a and Sp-b but have no deficit in surfactant phospholipid biosynthesis.¹⁰⁸

Given the broad distribution of pulmonary glucocorticoid receptors in the developing lung, it is not surprising that the therapeutic effects of glucocorticoid treatment are complex. Clinical experience suggests that glucocorticoids have contrasting biologic effects depending upon whether treatment is directed toward the fetal lung or the preterm neonatal lung. Women in preterm labor are routinely treated with glucocorticoids to reduce the incidence and severity of neonatal RDS.¹⁰⁹ Antenatal steroid treatment accelerates fetal lung maturation by inducing mesenchymal thinning and enhancing pulmonary function, presumably through stimulation of surfactant production. Morphometric studies in sheep suggest that antenatal steroid treatment may also induce some blunting of alveolarization.¹¹⁰ Glucocorticoid treatment has also been employed to treat preterm infants experiencing severe BPD. Although early studies and anecdotal reports suggested that steroid treatment could reverse the fibrosis and scarring associated with BPD and significantly improve pulmonary mechanics,¹¹¹ subsequent studies demonstrated no clear improvement in long-term pulmonary outcome and increased risk for neurodevelopmental impairment.¹¹²

TRANSCRIPTIONAL REGULATION OF LUNG DEVELOPMENT

The diffusible molecules mediating tissue interactions in the developing lung initiate signaling cascades that lead to changes in gene expression. The diversity of cell types found in the lung, which all differentiate under tight spatial and temporal control, makes regulation of gene expression by transcription factors in the developing lung highly complex. Although no lung-specific transcription factors have yet been found, research over the last decade has identified several transcription factors in addition to those described earlier that are crucial to normal lung development.

NKX2-1

NKX2-1 (also known as “*thyroid transcription factor 1*” [TTF1]) is found in the presumptive respiratory region of the foregut endodermal epithelium before lung bud induction. NKX2-1 is expressed in the forebrain, thyroid, and lung, where it interacts with multiple partners to influence several key aspects of development.¹¹³ Mice null for *Nkx2-1* develop tracheoesophageal fistulas, with main-stem bronchi connecting to hypoplastic, cystic lungs.¹¹⁴ Whereas differentiation of the most proximal epithelium is somewhat preserved in *Nkx2-1*-null lungs, markers of distal epithelial

differentiation, including the surfactant proteins, are completely lacking. Haploinsufficiency for the *NKX2-1* gene in humans leads to brain-lung-thyroid syndrome, which is characterized by benign hereditary chorea, respiratory disease, and congenital hypothyroidism.¹¹⁵⁻¹¹⁸ The respiratory phenotypes include RDS at birth, as well as recurrent pulmonary infections and interstitial lung disease later in childhood. The control of *NKX2-1* expression in lung development is not fully understood.

GLI Genes

Three *GLI* genes (1, 2, and 3) code for zinc finger transcription factors that are the principal effectors of hedgehog signaling. All three *Gli* genes are expressed in distinct but overlapping domains in lung mesenchyme, with expression being highest in the distal tips.^{119,120} The analysis of compound mutant mice has demonstrated the complexity of how *Gli* genes affect lung development. Embryos expressing different combinations of *Gli* genes show a range of lung defects, the most striking of which is the absence of lungs, trachea, and esophagus in *Gli2*^{-/-}, *Gli3*^{-/-} compound mutants.¹²¹ The presence of a single *Gli3* allele (*Gli2*^{-/-}, *Gli3*^{+/-}) is sufficient to allow formation of hypoplastic lungs in which the left and right lungs do not separate, and the embryos have tracheoesophageal fistulas. The phenotype seen in *Gli2/Gli3* double-null embryos is more severe than that seen in *Shh*-null animals; this suggests that the *GLI* genes may lie downstream in signaling pathways other than SHH, or that the other hedgehog proteins (Indian and desert) may be active in the lung. Mutations in the human *GLI3* gene cause Pallister-Hall and Greig syndromes, which affect development of several organ systems, including the lung.¹²²

FOX Family

The FOX family of transcription factors contains more than 50 members, all of which share a winged-helix DNA binding domain. FOXA1 and FOXA2 are closely related proteins found in the foregut endoderm and its derivatives. Their spatial and temporal expression patterns are similar in the lung. Mice lacking *Foxa2* do not form endoderm and hence cannot form lungs¹²³; targeted deletion of *Foxa2* in lung epithelial cells, however, demonstrates that it is required for alveolarization and epithelial cell differentiation.¹²⁴ Deletion of *Foxa1* in mice delays some aspects of sacculization and alveolarization prenatally and perinatally, but these differences normalize by 2 weeks of age,¹²⁵ suggesting compensation by *Foxa2*. Deletion of both genes inhibits cell proliferation, branching morphogenesis, and epithelial cell differentiation,¹²⁶ indicating that FOXA1/2 play a central role in lung development.

Foxa1 is expressed in lung mesenchyme and controls genes involved in epithelial-mesenchymal interactions, because a haploinsufficiency results in defective branching, lobation, and epithelial differentiation in the mouse lung.¹²⁷ In humans, FOXF1 mutations are associated with ACD/MPV.³³ Foxj1 controls expression of left-right dynein, which is required for correct anchoring of basal bodies; deletion of *Foxj1* causes situs inversus, the loss of motile cilia in airway epithelial cells, sinusitis, and bronchiectasis.¹²⁸ Although these features are associated with Kartagener syndrome in humans, no mutations in the FOXJ1

gene have been directly linked to this disorder. FOXP1 and FOXP2, which are known transcriptional repressors, are expressed in the lung epithelium; both genes are expressed distally, but only FOXP1 is expressed proximally. *Foxp2*^{-/-} mice show impaired alveolarization, an effect exacerbated in compound mutant *Foxp2*^{-/-}, *Foxp1*^{+/-} mice, which have hypoplastic lungs and die at birth. Foxp1 acts cooperatively with Foxp4 to restrict goblet cell specification, thereby regulating the balance of cell types in the airway epithelium.¹²⁹

GATA6

GATA6, a zinc finger transcription factor that is required for visceral endoderm differentiation,¹³⁰ is the only GATA family member expressed in the distal epithelium of the developing lung. Mice bearing a dominant-negative Gata6/engrailed fusion protein under control of the *Sftpc* promoter show reduced numbers of proximal airway tubules. Lung epithelial cell differentiation is also affected, with these mice completely lacking detectable alveolar type I cells.¹³¹ Loss of Gata6 in the lung epithelium causes a loss of differentiation and the precocious appearance of bronchioalveolar stem cells that is the result of increased Wnt signaling.¹³² GATA6 regulates expression of WNT7B and also interacts with NKX2-1 to control expression of SP-A, B, and C.¹¹³

SOX Family

Members of the SOX family of transcription factors function as key regulators of cell fate and differentiation. Of the 20 known SOX proteins, SOX2, 4, 9, 11, and 17 are found in the developing lung. Sox2 is highly expressed in non-branching epithelium but repressed by Fgf10 in epithelial cells that are actively invading the surrounding mesenchyme,¹³³ suggesting that silencing of Sox2 is required for the epithelium to branch. The repression of Sox2 by Fgf10 may be mediated by BMP signaling.⁸⁵ Overexpression of Sox2 in lung epithelial cells inhibits lung branching by forcing the cells to commit prematurely to a differentiation program, thereby rendering the cells incompetent to respond to branching signals.¹³⁴ Sox11 is also expressed throughout the developing lung epithelium, and mice null for *Sox11* have significant lung hypoplasia.¹³⁵ Sox17 expression in the lung is dynamic, being first detected in the mesenchyme during the embryonic stage, then in the conducting airway epithelium during the canalicular stage. Because its misexpression in the distal epithelium disrupts branching and causes the ectopic expression of proximal airway markers, Sox17 is thought to play a key role in specifying differentiation of airway epithelial cells.¹³⁶

POSTTRANSCRIPTIONAL GENE REGULATION IN LUNG DEVELOPMENT

Micro-RNAs (miRNAs) are small noncoding RNA molecules that modulate physiologic and pathologic processes by inhibiting gene expression through RNA translation repression or messenger RNA degradation. Functionally mature miRNAs are generated by a series of ribonuclease III cleavage steps. Key enzymes in miRNA biogenesis include DROSHA, which cleaves primary miRNAs into precursor miRNAs in the nucleus, and DICER1, which cleaves precursor

sor miRNAs to the mature form in the cytoplasm. Mature miRNAs are incorporated into the large multiprotein RNA-induced silencing complex, which represses RNA translation or induces messenger RNA degradation. miRNAs regulate key biologic processes important in lung development, including cellular proliferation, apoptosis, and differentiation. miRNA profiling reveals that the lung has a specific miRNA expression profile that is conserved across species (including mouse and human) and regulated specific to developmental stage, sex, and cell type.¹³⁷⁻¹⁴⁰ miRNAs have a critical role in controlling organogenesis. Loss- and gain-of-function studies, as well as differing expression profiles between patients or animal models with lung disease and normal controls, implicate miRNAs in the pathogenesis of many lung diseases, including chronic obstructive pulmonary disease, lung cancer, pulmonary inflammatory disease, idiopathic pulmonary fibrosis, asthma, and cystic fibrosis (for reviews see references 141 to 144). Additionally, studies in model systems have identified a critical role for miRNA-mediated regulation in lung development. Inactivation of *Dicer1*, a key enzyme in miRNA biogenesis, targeted to the developing lung epithelium results in neonatal death because of arrested airway-branching morphogenesis, increased cell death, and altered expression of critical epithelial-mesenchymal signaling molecules.¹⁴⁵ Specific miRNAs that have been identified to influence lung development include the miR302/367 cluster that directs lung endoderm development by coordinating proliferation, differentiation, and apical-basal polarity of lung progenitor cells,¹⁴⁶ the miR17-92 cluster that is required for lung growth as well as for promoting proliferation and inhibiting differentiation of lung epithelial progenitor cells,^{147,148} miR127, which regulates terminal bud size and number,¹⁴⁹ and miR221 and miR130a, which have opposing effects on airway and vascular morphogenesis.¹³⁷ The recent discovery of heterozygous germline loss-of-function *DICER1* mutations in familial *pleuropulmonary blastoma* (PPB), a rare pediatric lung tumor that often arises during lung development, provides evidence that the *DICER1*/miRNA pathway controls human lung development and suppresses tumorigenesis.¹⁵⁰ The majority of car-

riers with *DICER1* mutations are phenotypically normal, suggesting that loss of one *DICER1* allele is compatible with normal development and insufficient for tumor formation. PPB is composed of both epithelial and mesenchymal cells.^{151,152} In a subset of patients, overgrowth of the mesenchymal cells results in a sarcoma that is associated with a poorer prognosis. Interestingly, the protein DICER1 was found to be lost in the epithelial tumor component but retained in the mesenchymal cells by immunohistochemistry, suggesting that loss of DICER1 specifically in the lung epithelium promotes PPB formation.¹⁵⁰ Consistent with this notion, *Dicer1* gene ablation targeted to the developing murine pulmonary epithelium results in a PPB-like phenotype (Fig. 2-3). Because PPB often arises in the setting of an inherited tumor predisposition syndrome characterized by increased incidence of other neoplasms, including cystic nephroma, ovarian sex cord-stromal tumor, embryonal rhabdomyosarcoma, and multinodular goiter, the *DICER1*/miRNA pathway functions that control lung development are probably also operative in other organs.¹⁵³⁻¹⁵⁵

Key Points

- The lung epithelium begins as two buds from foregut endoderm. Subsequent branching morphogenesis and alveolarization leads to a mature organ containing over 300 million alveoli.
- The pulmonary vasculature develops in parallel with the branching epithelium.
- Lung development requires reciprocal interactions between the epithelium and mesenchyme derived from splanchnic mesoderm.
- Tissue interactions are mediated by an array of diffusible signaling molecules. Variations in the temporal and spatial expression of these mediators add complexity to these interactions.
- Diverse classes of transcription factors that lie downstream of diffusible mediators further regulate morphogenesis and effect the differentiation of individual cell types.

Figure 2-3 Mouse lungs with *Dicer1* loss mimic pleuropulmonary blastoma (PPB) in neonates. Human PPB (**B** and **C**), adjacent normal neonatal lung (**A**), *Dicer1*-deficient mouse embryonic day 18.5 lungs (**E** and **F**), and normal lungs from *Dicer1*-proficient littermates (**D**) were compared by hematoxylin and eosin staining. PPB and *Dicer1*-deficient murine lung sections were also immunostained for the type I cell marker, T1α (**C** and **F**), to determine the phenotype of the epithelial cells lining the cysts. **A** and **D**, The neonatal human lung adjacent to the tumor shows normal morphologic characteristics for the alveolar stage of lung development, and the mouse lung shows morphologic characteristics typical of the saccular stage of development. **B**, Early-stage type I PPB is characterized by epithelium-lined cysts with intervening septa containing mesenchymal cells. **E**, The *Dicer1*-deficient mouse lungs have morphologic characteristics similar to those of human PPB, including epithelium-lined cysts separated by septa containing mesenchymal cells. Many of the epithelial cells lining the PPB cysts have a type I cell phenotype as determined by expression of T1α (**C**). Similarly, the *Dicer1*-deficient epithelial cells lining the cysts in the murine model also express T1α (**F**). (**A** and **B**, $\times 4$ original magnification; **C**, $\times 20$ original magnification; **D** and **E**, $\times 10$ original magnification; **F**, $\times 40$ original magnification.)

THE PATH FORWARD

INTRODUCTION

The human genome comprises approximately 3.2 billion base pairs. With the exception of identical twins, each human being has a unique DNA sequence. There are at least 10 million locations in the genome where DNA sequence varies between individuals. These locations are referred to as “polymorphic” when at least two variants (also known as “alleles”) are present at a frequency greater than 1%. Most human diseases are the result of the interplay between these genetic polymorphisms and environmental exposures. The first step in any investigation of the genetic causes of a disease or phenotype is to determine the relative importance of these two causes of the disorder among the population of interest. To begin this process, one must determine the heritability of the disease of interest. Heritability is defined as the percentage of phenotypic variation that is due to variation in genetic factors. Often the first step is to determine if the trait, disease, or phenotype aggregates in families, but this will not prove that the trait of interest is genetic because traits can aggregate in families for purely environmental reasons, such as cigarette smoking, or because the prevalence of the trait is high, such as obesity. The most direct way to estimate the contribution of genetic variation to a disease is to measure heritability. Heritability can be estimated using families. For example, in twin studies a greater concordance of the phenotype between identical (monozygotic) twins than fraternal (dizygotic) twins can provide evidence of heritability of that phenotype. For lung disorders, heritabilities range from 20% to 90% depending on the type of lung disease, the mode of inheritance, and the degree of environmental influence.

There are two primary types of genetic disorders, monogenic (due to variation in a single gene) or complex (due to variation in multiple genes). Monogenic disorders demonstrate high heritability, segregate in families in a predictable way, and are caused by variation in a single major gene with less obvious environmental influence. The single gene usually has specific variation in the coding region of the gene that leads to an abnormal protein that causes an obvious clinical phenotype. Often the phenotype has multiple components, suggesting multiple effects of the gene

variant(s). This is called “pleiotropy,” in which one variant has many effects. There are currently over 10,000 monogenic disorders that have been identified and are characterized in the Online Mendelian Inheritance in Man (<http://www.ncbi.nlm.nih.gov/sites/entrez?db=omim>). Positional cloning (linkage mapping followed by association mapping; described later) has been the primary means of the identification of these genetic variants until recently. With the completion of the Human Genome Project and the rapid advancement of genotyping technologies, attention has turned to identification of genetic variation associated with complex genetic disorders. Those efforts initially used positional cloning but now primarily rely on genetic association studies.

In contrast to monogenic disorders, complex genetic disorders are caused by variation in multiple genes and multiple environmental exposures, with each genetic variant having a much smaller effect than those seen in monogenic disorders. Because of the multiple gene-gene and gene-environment interactions, there is no obvious mendelian mode of inheritance in families for complex traits. One of the most prominent hypotheses for the genetic basis of common disease is the common disease/common variant hypothesis. This hypothesis suggests that key genetic determinants of common diseases have a relatively high allele frequency (i.e., 5% to 40%) and modest effect sizes. Given the modest effect sizes (odds ratios on the order of 1.1 to 1.4), large sample sizes are necessary to identify the genetic variants associated with complex traits despite the high allele frequency expected in these disorders. It is likely that there is a range of allele frequencies that predispose to complex diseases, with a corresponding range of effect sizes, but large-scale studies to evaluate the evidence for rare variation as a contributor to complex disease are only beginning to emerge.

The dichotomy described earlier between monogenic and complex disease is somewhat artificial because the clinical phenotype of many monogenic disorders varies as a result of the specific mutation present, other modifier genes, and environmental exposures. As genes for complex traits begin to be identified, their role in monogenic disorders is also being elucidated.

SCOPE OF THE PROBLEM

Some complex genetic disorders, such as age-related macular degeneration, are oligogenic, in which a small number of genes, three to five, explain the bulk of the clinical phenotype. However, for most complex traits, literally hundreds of genes with small effects are likely involved in disease causation. Thus a series of challenges have faced complex trait geneticists in the genome era of medicine.

The field of human genetics has continued to expand as the type of genomic variation that can be measured expands. Parallel advances in data analysis strategies are necessary to ensure efficient and valid inferences based on the ever-increasing volume of data that can be collected on large numbers of individuals. This cyclical pattern of advancement has been typical of the last several decades and is likely to be typical going forward. For example, initial problems relating to genotyping reliability and completeness for common variants (those with frequency > 5% in a given population) that were present at the time of release of the initial sequence of the genome have been largely resolved, as have the methods necessary to detect and control for population stratification (confounding by allele frequency differences in cases and controls, discussed later) and to account appropriately for the hundreds of thousands or millions of tests conducted in a genome-wide association study. Since 2010, large efforts have been focused on resequencing technologies, which sequence the same site in multiple individuals to capture sequence variation and thus capture uncommon and rare variation (frequency ≤ 5%). As we are able to measure a larger variety of genomic data (e.g., transcriptomic and epigenetic data) on ever-increasing numbers of individuals, the major analytic challenges will be in developing methods for integration of the different types of data. For all types of genetic variation, the ability to determine if genetic effects are real or not requires replication of results in independent populations, a process that can be difficult with the presence of phenotypic heterogeneity across populations. In particular, varying genetic backgrounds and environmental influences can result in variability in the effects of genetic variants across populations. Finally, the ultimate challenge of finding and verifying the functional variants in putative disease genes is still a laborious process without a clear-cut methodology for success.

POTENTIAL IMPACT OF HUMAN GENETICS

Genetics has the potential, because of its hypothesis-free nature, to identify novel mechanisms of disease pathobiology and hence to identify novel targets for a therapeutic intervention or disease prevention. In addition, genetics has the potential to predict specific subgroups of patients with a different clinical course or response of their disease, or differences in treatment. Finally, genetics has the potential to allow for early detection of susceptible individuals at risk for a specific disease phenotype or to allow avoidance of environmental factors that are known to cause the disease or to institute preventive therapy before disease develops. These genetic insights are still just beginning to be applied, and it will take time for genetics to become routinely used at the bedside.

MOLECULAR CHARACTERIZATION OF GENETIC VARIATION

Molecular genetics is elegant in its simplicity. Just four base pairs (two purines [adenine and guanine] bind to two pyrimidines [thymine and cytosine]) code for 20 amino acids that form the molecular building blocks of complex proteins. However, the assemblage of inherited genes (genotypes), control mechanisms, resultant proteins, and post-translational modifications have the capacity to create a complex panoply of unique biologic, physiologic, or visible traits of an organism (phenotypes). The relationship between these rather simple molecular characteristics and the vast array of complex phenotypes is, in part, explained by a number of seminal discoveries that were made more than 50 years ago.

Gregor Mendel¹ was the first to demonstrate that discrete traits could be inherited as separable factors (genes) in a mathematically predictable manner. Mendel's laws describe the relationship between genotype and phenotype and established the concept that each gene has alternative forms (alleles). Charles Darwin² made the observation that evolution represents a series of environmentally responsive "genomic" upgrades. Thomas Morgan³ established the concept of linkage by using *Drosophila* to discover that genes were organized (and inherited) on individual chromosomes, and that genetic material was recombined or exchanged between maternal and paternal chromosomes during meiosis and that the frequency of recombination could be used to establish the relative genomic distance between genes. However, it was not until 1944 that Avery, MacLeod, and McCarty while working with *Pneumococcus* discovered that DNA was identified as the essential molecule that transmitted the genetic code.⁴ The double-helix structure of DNA was discovered by Watson, Crick, Chargaff, Franklin, and Wilkins in 1953,⁵ and over the next 50 years genetics assumed a central role in understanding the biologic and physiologic differences between and among species and between states of health and states of disease. In aggregate, these seminal discoveries led to a number of fundamental principles in molecular genetics that provide the basic mechanisms that link the four base pairs (adenine [A] binding to thymine [T] and guanine [G] binding to cytosine [C]) to health and disease.

GENOMIC MAPS

Over the past several decades genomic maps have evolved from karyotypes (microscopic visualization of chromosomes during metaphase) to restriction enzyme sites to genetic maps to maps with specific base pair sequence. In fact, to date there are hundreds of vertebrate, invertebrate, protozoan, plant, fungal, bacterial, and viral genomes that have been sequenced and are available on the National Center for Biotechnology Information (NCBI) Web site (www.ncbi.nlm.nih.gov). These genomic maps have not only been essential for identifying which genes and sequence changes cause disease or enhance the risk for adverse outcomes, these species-specific maps have also led to a very clear understanding of molecular evolution and have provided essential tools for understanding aspects of molecular

Table 3-1 Commonly Used DNA Markers

Restriction fragment length polymorphisms—Presence or absence of a specific nucleotide sequence that can be cleaved by a restriction enzyme. These bacterial restriction enzymes fragment DNA only at sites that contain very specific base pair sequences.

Variable number of tandem repeat polymorphisms—Noncoding polymorphic base pair repeats in DNA (dinucleotide, trinucleotide, and tetranucleotide repeats of CA or GT) that are present throughout the genome. At each site the number of times a sequence is repeated may vary from one individual to the next.

Microsatellite polymorphism—Variable number of repetitions of a small number of base pairs within a sequence.

Single nucleotide polymorphisms—Individual point substitutions of a single nucleotide that do not change the length of the DNA sequence and are present throughout the genome (every several hundred base pairs).

A, adenine; C, cytosine; G, guanine; T, thymine.

biology. The construction of these genomic maps is based on the observation that the sequence of DNA is different from one organism to the next within the same species, and these allelic/sequence differences have been exploited to develop a number of commonly used DNA markers to create genomic maps (Table 3-1).

Genetic maps are based on the frequency of recombination events, defined as a specific form of exchange of genetic material between the maternal and paternal chromosomes during meiosis. Although Mendel's second law states that traits (or genes) are inherited independently, we now know that some genes do not segregate independently because they are on the same chromosome. Humans have 24 linkage groups, corresponding to the 22 autosomes, plus X and Y chromosomes. Genes on the same chromosome that are closer together are more likely to be inherited together (linked) than genes that are farther apart, which may demonstrate independent assortment. In general, the greater the distance between genes on the same chromosome, the higher the recombination frequency (Fig. 3-1). Thus the recombination frequency represents a measure of genetic linkage and is the fundamental event used to create a genetic linkage map. The unit of measurement for genetic linkage maps is the *centimorgan* (cM), with 1 cM equivalent to a recombination frequency of 1% (one recombinant event per 100 meioses). Although recombination frequencies vary across the chromosome, in general, at least for the human genome, a recombination frequency of 1% is equivalent to approximately 1 million base pairs. Genetic maps are constructed by identifying the number of recombinant events observed in parental meioses and are dependent on several factors: (1) the meioses observed, (2) the heterozygosity of the marker, (3) the physical distance between markers, and (4) the likelihood of recombination at that site. Genetic maps use a rather indirect method to estimate the order of genes and the relative distance between genes.

Genetic maps are routinely used in family-based linkage studies to identify the general location of genes that influence human traits and conditions. Highly polymorphic markers can be used as tags to identify regions of DNA that are linked with a disease locus in families. These regions (often 20 to 40 cM in length) of DNA then serve as the targets to interrogate via association studies. However, a

Figure 3-1 Crossover between homologous chromosomes in meiosis. On the left is an example in which two loci are far apart on the chromosomes and so remain unlinked. On the right the loci are relatively close to one another and so, after recombination, are more likely to remain together.

genetic linkage map should not be confused with a physical map of the genome because genetic maps are based on the rate of recombination, not the physical distance, between markers, although these two features are related.

In contrast to a genetic map, a physical map describes the physical location of genes and the physical relationship between genes on each chromosome. Although the gene order from a genetic map and a physical map should theoretically be the same, the relative distance between genes may be quite different when comparing a genetic map (based on recombination frequency) to a physical map (based on genetic distance along the chromosome). The reason for this discrepancy is that the recombination rate across chromosomes is not constant. However, genetic maps provided the first framework for the construction of physical maps.

Although we typically think of physical maps as sequence based, many years before sequence-based maps became available, investigators relied on lower-resolution cytogenetic (chromosomal) and radiation hybrid maps. Cytogenetic maps are based on chromosomal banding patterns and have been used to locate genes in patients with chronic granulomatous disease, Duchenne muscular dystrophy, and fragile X syndrome.

Two major breakthroughs at the end of the 20th and beginning of the 21st centuries changed human genetics

forever—the sequencing of the human genome^{6,7} and the creation of the International HapMap Project to identify the common sequence differences and similarities between individuals.⁸ With the sequencing of the human genome, investigators for the first time had a detailed road map of the human genome that identified the genes, regulatory units, and noncoding sequence with a very high degree of resolution. Of the 3.2 billion base pairs in the human genome, less than 1% uniquely identify each human being.⁹ There are approximately 12 million *single nucleotide polymorphisms* (SNPs) in the human genome. These are single base pair changes that result in allelic variation at a locus. Although only a small proportion of these SNPs will result in amino acid changes, these SNPs provide some of the genetic diversity that underlies the variable susceptibility to environmental stimuli and the variable risk for disease development and progression.⁹ Although the initial HapMap project focused on populations from African, Asian, and European ancestry, more recent work expanded the collection to include a wide variety of ancestry groups. Because the HapMap project was focused on common variation, the 1000 Genomes Project¹⁰ was developed to catalog uncommon and rare variation among human populations using resequencing. Like the HapMap project, this publically available resource provides the empirical data necessary for scientists to design disease-specific studies aimed at understanding the role of uncommon and rare variation.

In aggregate, the human DNA sequence and the shared genetic patterns between individuals have enabled geneticists to define the organization of genetic variants on chromosomes and the common inheritance of genetic variants. These developments have provided the polymorphic markers and the regions that are tagged to these markers to facilitate the identification of regions and genes that contribute to risk for disease. Consequently, real progress is now being made in identifying common and rare genetic variations that contribute to complex diseases such as asthma,¹¹ age-related macular degeneration,¹² type 2 diabetes,¹³ and prostate cancer.¹⁴

COMPARATIVE GENOMICS

Because DNA structure and protein functions are often conserved through evolution, the use of model organisms can enhance the efficiency of gene discovery and can provide insights into biologic responses to endogenous and exogenous forms of stress. Although genes present in humans often have counterparts in other species, the homology between gene and chromosomal structure across species does not necessarily lead to conserved protein function. However, the conservation of gene sequence and chromosomal structure in different organisms has resulted in accelerated gene discovery, insights into human biology, and a data-driven understanding of evolution. Despite this excitement, the field of comparative genomics is at a very early stage of development¹⁵ and is dependent on evolving databases, like Gene Ontology functional classifications,¹⁶ to facilitate these cross-species comparisons.

Comparative genomics is a powerful approach to searching for disease-causing genes. Identifying similar regions of DNA associated with concordant phenotypes in multiple species enhances the confidence that a gene causing that

disease resides in that locus. The overlapping DNA for concordant phenotypes between species can be used to narrow the region of interest substantially. Because there are approximately 340 known conserved segments between mice and humans,¹⁷ a mouse region of interest associated with a trait can be used to narrow the human region of interest associated with a disease. Additionally, the genomes of model organisms, such as mice, flies, worms, or yeast, can be manipulated through genetic engineering (resulting in deficiency or overexpression of a gene, or controlled expression of a human allele) to understand the function of a specific gene. For example, the importance of the Toll-like receptors in innate immunity in mammals was discovered as a direct result of the observation that a defective receptor in flies caused them to be much more susceptible to *Aspergillus fumigatus*.^{18,19} The importance of this finding is clearly illustrated in the variations in the Toll-like receptors that alter the response to microbial pathogens²⁰ and modify the risk for developing a variety of diseases that are associated with innate immunity.²¹ The ease with which we can observe and apply knowledge across model systems should be exploited so that we can efficiently understand the biologic and clinical importance of key regulatory genes.

PUBLIC DATABASES

If compiled in books, the data produced in defining the human genome would fill 200 volumes, each the size of a 1000-page phone book. Reading it would require 26 years working around-the-clock. Although new tools are being developed to analyze, store, and present the data from genome maps and sequences, several databases presently exist that can be accessed through the Internet.

Important lessons can be learned from a detailed consideration of the characteristics of identified mutations in mendelian diseases using online resources such as the Online Mendelian Inheritance in Man, the Human Gene Mutation Database, and LocusLink.²² For example, the data on the relative frequency of types of mutations underlying disease phenotypes indicate that mendelian disease genes most often have alterations in the normal protein-coding sequence. For general information on accessing sequence information, several available reviews provide details on available databases and searching strategies.²³ The NCBI is responsible for the final and reference assembly of the human genome. Each DNA sequence is annotated with sequence features and other experimental data, including location of SNPs, expressed sequence tags, and clones. Up-to-date genetic sequence information can be obtained from Ensembl (<http://www.ensembl.org>), the University of California at Santa Cruz Genome Browser, and the NCBI's GenBank. The NCBI's Map Viewer provides a tool through which genetic maps and sequence data can be visualized and is linked to other tools such as Entrez, the integrated retrieval system providing access to numerous component databases. The database of Single Nucleotide Polymorphisms at the NCBI allows the user to search for SNPs within a region of interest (<http://www.ncbi.nlm.nih.gov/SNP>). The HapMap (<http://hapmap.ncbi.nlm.nih.gov/>) and 1000 Genomes (<http://www.1000genomes.org/>) databases provide raw and summary genotype and linkage

disequilibrium data about common and rare genetic variation across several racial and ethnic groups.

GENETIC EPIDEMIOLOGY

POSITIONAL CLONING

Advances in our understanding of the variation across the human genome have allowed wide application of the positional-cloning approach to identification of genetic variants that contribute to phenotypes of interest. Positional cloning refers to identification of a chromosomal position that is related to the phenotype based on scanning the genome for a relationship between each locus and the phenotype, rather than relying on the known biochemical properties of a gene to identify it as a candidate for being related to the phenotype. The first approach to positional cloning relied on linkage analysis, most often followed by association analysis; since 2007, genome-wide association analyses have been the standard positional-cloning approach. Whole-exome resequencing studies are now feasible for sample sizes in the hundreds, and whole-genome resequencing studies are rapidly decreasing in cost.

LINKAGE STUDIES

Linkage analysis encompasses a group of statistical methods to examine the inheritance pattern of DNA markers within families to determine if there is a relationship between a particular region of the genome and a phenotype of interest. Most linkage studies have been based on short tandem repeat (repeats of a short sequence of nucleotides) or SNP markers distributed through the genome.

Linkage analyses use family data, which can be made up by a wide range of pedigree structures from extended pedigrees to affected sibling pairs. There are two broad types of linkage analysis, parametric and nonparametric; both rely on the coinheritance of disease alleles with genetic markers used in the analysis. When a mutation arises on a particular chromosome, initially there is a large shared segment of DNA and hence linkage disequilibrium around it. With each subsequent generation, this region of linkage disequilibrium becomes smaller as a result of meiotic recombination. The basic approach in parametric linkage analysis is to determine if alleles at a genotyped marker segregate with the alleles at a putative disease locus together more often than one would expect by random assortment, or chance. This can be assessed by comparing the frequency of recombinant chromosomes in which a crossing over event has rearranged the parental chromosomes to the frequency of nonrecombinant chromosomes. When two loci are linked, parental chromosomes are more common than recombinant chromosomes. The strength of the linkage between a marker and a putative disease locus is expressed as the recombination fraction. Parametric linkage analyses require that a particular genetic model be specified. Thus the approach is ideal for classic mendelian, monogenic disorders but is less well adapted for complex traits, where these parameters are often not known. Nonparametric linkage analysis refers to a group of analysis methods that, in contrast to parametric linkage analysis, do not require assump-

tions about a particular form of inheritance. The general approach for nonparametric linkage analysis is to contrast observed allele sharing between affected relatives to that expected given their relationship (e.g., siblings) at a given locus. Regions that show statistically significant excess sharing among affected relatives are regions that may harbor loci important for the phenotype of interest. This nonparametric approach has been combined with genetic association within the linked region to identify disease susceptibility genes for asthma, Crohn disease, and pulmonary fibrosis.²⁴⁻²⁹

Linkage results are usually expressed as an LOD score, which is a function of a statistical test for linkage. LOD scores are log of base 10 of the odds that the loci are linked, and their distribution depends on the study design.

ASSOCIATION STUDIES

Genetic association studies are the most commonly used study designs to find disease genes in complex traits. Association studies can be used in conjunction with linkage studies, *de novo* with candidate genes or *genome wide association studies* (GWAS). There are two basic types of study designs used for genetic association studies, the case-control study and the family-based study; both types rely on the concept of linkage disequilibrium between the alleles at a genotyped marker(s) and the disease allele(s).

When two SNPs are on separate chromosomes, they will segregate randomly (i.e., carrying the minor allele at SNP A does not affect your chances of carrying the minor allele at SNP B). If, on the other hand, the alleles at the SNPs are in linkage disequilibrium, with little or no recombination between them, the genotype at SNP B can serve as a surrogate for the genotype at SNP A. Thus testing of all SNPs in a gene or a region of the genome is unnecessary. One need only genotype a subset of SNPs to capture the linkage disequilibrium pattern among common variants (>5%) of the region of interest to be comprehensive. Importantly, detecting phenotype association with a genetic marker does not indicate that the genetic marker is causally related to the phenotype, but may only reflect linkage disequilibrium with the causal variant.

Case-control studies are the most frequently performed type of genetic association studies because they are simpler to implement than family-based designs. In their simplest form, population-based genetic association studies are similar to epidemiologic case-control studies and involve identifying genetic markers with significant allele, genotype, or haplotype frequency differences between individuals with the phenotype of interest (cases) and a set of unrelated control individuals.³⁰ A statistical association between genotypes at a marker locus and the phenotype can arise for three reasons: (1) the allele is the actual disease allele, (2) the allele being studied is in linkage disequilibrium with the true disease allele, and (3) there is a spurious association due to population stratification. Indeed, case-control genetic association studies have already contributed to identifying genes associated with complex disorders, as in the cases of apolipoprotein E-4 with late-onset Alzheimer disease³¹ and factor V gene with venous thrombosis.³² Thus, performing valid case-control studies remains important in elucidating genetic risk factors for complex

traits. Silverman and Palmer³³ have reviewed these factors that may adversely affect the results of any association study in complex diseases. They have recommended five key elements in the performance of valid case-control genetic association studies for complex diseases: (1) proper selection of gene polymorphisms, (2) accounting for population stratification, (3) assessment of Hardy-Weinberg equilibrium, (4) replication, and (5) adjustment for multiple comparisons.

Ideally, cases and control study subjects should be drawn from the same base population. Failure to do so will often result in biased selection that can adversely influence the results, often resulting in a spurious association. When subjects with different evolutionary histories and hence different genetic backgrounds are differentially selected to be cases and controls, this can cause spurious results, termed “population stratification.” An approach useful in case-control studies to control this problem is to detect and control for population stratification in case and control groups by genotyping randomly distributed polymorphic markers.^{34,35} If population stratification is demonstrated between the case and control populations, methods to detect significant disease gene associations have been developed based on correction for the degree of stratification.³⁵⁻³⁸ A second major problem with early case-control studies has been that often too-small sample size is used to allow for robust evaluation of the evidence for association. Because of the small genetic effect sizes seen and expected for complex traits, sample sizes in the thousands are generally required in addition to replication to generate rigorously validated association results.

Family-based genetic association tests are based on the transmission disequilibrium test, which provides a test of linkage and association without bias from population stratification or admixture.^{39,40} For the transmission disequilibrium test, parents and an individual offspring (child or proband) with the disease phenotype are recruited. Only trios with at least one heterozygous parent at the genetic marker of interest are used for testing. The test is predicated on the assumption that if a genetic locus is uninvolved (neither linked nor associated) in the phenotype of interest, one would expect the two parental alleles at that locus to be transmitted equally to an affected child (i.e., mendelian, transmitted 50% of the time). However, if the locus is actually linked and associated with disease, there will be overtransmission (or undertransmission) of one allele at that locus—and its transmission will differ significantly from the expected 50%.

Family-based association studies cost more than case-control studies because one has to recruit and genotype three people instead of two. In addition, not all diseases can use the family-based design because often parents have died and hence are not available for study. Despite these disadvantages, there are also powerful reasons to use trios if possible. First, unlike the case-control study, the family-based association study is immune to population stratification because the parental genotype is used as the control. Second, within each trio, only one person (the subject) must be phenotyped. This is particularly useful when phenotyping is very expensive or invasive. Family-based testing also offers an important method of assessing genotyping quality, because data can be analyzed for mendelian errors. The

transmission disequilibrium test has been extended in many ways, for instance, to allow family-based tests of association for extended pedigrees.⁴¹⁻⁴⁶

GENOME-WIDE ASSOCIATION STUDIES

In GWAS, SNPs are selected to cover as much of the genome as possible. SNPs across all chromosomes and most genes are selected to assess association with a phenotype of interest. There are two currently two companies, Affymetrix and Illumina, which have different SNP selection strategies and different chip chemistry for performing GWAS. Both platforms provide excellent coverage of common variants across the genome for most racial/ethnic groups based on millions of markers.

GWAS are the standard approach to identification of phenotype-associated common genetic variations, and there are well-accepted approaches to the design, data collection, data cleaning, and data analysis required for these large, complex studies. The approximate cost for the most recent genotyping platforms is about \$250 per subject with a per-SNP cost of less than 1 cent. Although this genotyping cost is reasonable, the large sample size required for these studies results in millions of dollars for a single case-control study. In addition, the computational speed and electronic storage capacity required for the data analyses increase the cost of the studies. The investment in these studies has yielded great insight into complex disease genetics, because the number of robustly associated genetic loci for complex diseases has increased dramatically between 2000 and 2013.

GENE BY ENVIRONMENT INTERACTION

Since both genes and environmental exposures are known to be related to complex traits, performing studies to test both factors in one study design is of great value. Both family-based and case-control designs allow for testing for association while considering both the genetic and environmental exposures and perhaps their interaction. The two major challenges for these studies are statistical power and accurate measurement of exposure. Tests for gene-environment interaction require larger sample sizes than tests for the genetic effect alone.

Much has been made of the difficulties of accurately measuring the environment as an exposure for genetic association studies. Although some environmental factors such as diet are hard to measure accurately and require complex techniques, other exposures such as lifetime cigarette smoking can be measured with relatively high precision. Accurate measures of exposure will greatly enhance the ability of these studies to provide new insights into disease pathogenesis. It will likely be challenging to replicate these types of studies because finding several studies with similar exposures measured in similar ways is often impossible.

EPIGENETICS

Epigenetics is the study of changes in gene transcription that are dependent on the molecules that bind to DNA,

rather than the base-pair sequence of DNA.^{47,48} This includes both heritable changes in gene expression in the progeny of cells or of individuals and stable, long-term alterations in the transcriptional potential of a cell or tissue that are not necessarily heritable. Because epigenetic processes are highly interdependent and regulate gene expression in an age-, state-, cell-, and tissue-dependent manner, collectively these mechanisms constitute a complex system of molecular controls that affects biologic processes and human diseases.

Although the fundamental mechanisms of epigenetics continue to evolve, it is recognized that epigenetic regulation of the genome results in a hierarchy of transcriptional switches that facilitate development and differentiation, normal tissue function, and the ability of the host to respond to stress.^{47,48} There are three primary mechanisms that are known to govern gene expression (DNA methylation, histone modifications, and noncoding RNAs) and may be inherited, independent of the sequence of DNA (Table 3-2 and Fig. 3-2). DNA methylation is controlled by cytosine-methyltransferase, which transfers the methyl group from *S*-adenosylmethionine to the C-5 position of cytosine. Hypermethylation of cytosine-guanosine motifs, particularly at promoter and enhancer sites, silences gene transcription. Alternatively, hypomethylation of these motifs enhances gene transcription. Histones, the building blocks of nucleosomes, undergo numerous posttranslational mod-

ifications (methylation, acetylation, or phosphorylation with > 100 conserved, covalent modifications) that affect chromatin structure and alter gene expression. Noncoding RNAs bind to DNA and interfere with transcription and posttranscriptional regulation of gene expression. In aggregate these mechanisms serve to regulate the transcriptional activity of specific genes, at specific stages of development, and in response to specific forms of endogenous and exogenous stress. Importantly, these mechanisms are conserved in eukaryotic organisms, from yeast to humans.

Table 3-2 Known Epigenetic Mechanisms

DNA methylation—The methyl group is transferred from *S*-adenosylmethionine to the C-5 position of cytosine by a cytosine-methyltransferase. Hypermethylation of CpG motifs, particularly at promoter and enhancer sites, silences gene transcription. Alternatively, hypomethylation of these motifs enhances gene transcription.

Histone modification—Histones, the building blocks of nucleosomes, undergo numerous posttranslational modifications (methylation, acetylation, or phosphorylation with > 100 conserved, covalent modifications) that regulate chromatin structure and gene expression.

Noncoding RNAs—Bind to DNA and interfere with transcription and posttranscriptional regulation of gene expression (e.g., miRNA).

CpG, cytosine-guanosine; miRNA, micro-RNA.

Figure 3-2 Effect of epigenetic marks on gene expression. Epigenetic mechanisms include DNA methylation, modification of histone tails, and generation of non-coding RNAs. Each of these can affect gene expression. The top panel shows how these three epigenetic mechanisms can increase gene expression; the bottom panel shows how these three epigenetic mechanisms can decrease gene expression. Blue arrows indicate crosstalk between DNA methylation and histone modifications. The relationship between histones and DNA methylation is bidirectional; in addition to histones playing a role in the establishment of DNA methylation patterns, DNA methylation is important for maintaining patterns of histone modification through cell division. mRNA, messenger RNA. (From Yang IV, Schwartz DA: Epigenetic control of gene expression in the lung. *Am J Respir Crit Care Med* 183:1295–1301, 2011. Epub 2011;May 21. Reprinted with permission of the American Thoracic Society.)

Epigenetic mechanisms can have profound effects on cellular, tissue, and whole-organism phenotype. Phenotypes that are known to be affected by epigenetic regulation include fundamental mechanisms such as stem cell differentiation⁴⁹ and inactivation of the X chromosome,⁵⁰ carcinogenesis⁵¹ and cancer prognosis,⁵² and even basic aspects of learning and memory.^{53,54} Moreover, genomic imprinting (epigenetic mechanisms that lead to preferential expression of either the maternal or paternal allele) has been shown to be the cause of rare genetic anomalies such as the Prader-Willi, Angelman, Beckwith-Wiedemann, and Silver-Russell syndromes.

Although epigenetic marks (i.e., methylation changes and histone modifications) can be inherited, these potent regulators of transcription can also be modified throughout development⁵¹ and by the environment.⁵⁵ For instance, although monozygotic twins are genetically identical, twin pairs often differ in phenotype (anthropomorphic features as well as disease outcomes). Global and locus-specific differences in DNA methylation and histone acetylation patterns indicate that early in life, monozygotic twins are epigenetically identical, whereas older twin pairs have divergent epigenetic marks that are associated with differences in gene expression.⁵¹ These findings suggest that various life events can alter epigenetic marks that may account, in part, for these phenotypic differences in twin pairs. Moreover, environmental endocrine disruptors (methoxychlor and vinclozolin) have been shown to induce transgenerational effects on male fertility as a result of DNA methylation.⁵⁵ In aggregate, these findings suggest that the epigenome can be reprogrammed, potentially affecting the risk, cause, and treatment of various disease states.

The technology to measure epigenetic changes is continuing to evolve, and, with the advent of methylation sequencing, it will soon be feasible to detect the epigenetic modifications of the entire genome during states of stress and disease. DNA methylation has been traditionally evaluated using methylation-sensitive restriction enzymes in conjunction with Southern blot analysis. However, this labor-intensive approach has been largely replaced by bisulfite modification of DNA that deaminates unmethylated cytosines to uracils without affecting methylated cytosines. The cloned region of DNA is then amplified by polymerase chain reaction and sequenced, with the unmethylated cytosine (which was converted to a uracil) being replaced by a thymine and the methylated cytosine amplifying as a cytosine. Methylation-specific PCR, a method that uses primers specific for methylated or unmethylated genomic DNA, has higher throughput but is unable to detect the exact pattern of DNA methylation. Thus more global approaches, such as methylation-specific digital karyotyping,⁵⁶ array-based methylation hybridization, or methylated DNA immunoprecipitation coupled with either tiling arrays that include most of the human promoters or pyrosequencing are now being used. Functionally relevant methylation changes can be investigated using demethylating agents followed by expression microarrays. However, the expression changes induced by demethylating agents could also be caused by indirect effects of the drug.

High-quality antibodies have been used to detect known modifications in the amino acid residues of histones. Although these antibodies can be used for Western blot

analysis, they are more commonly used in a chromatin immunoprecipitation assay to measure the concentration of specific histone modifications at specific loci. Chromatin immunoprecipitation can be used in conjunction with either microarrays (chromatin immunoprecipitation–chip) or pyrosequencing (chromatin immunoprecipitation–sequencing) to evaluate global changes in histone modifications. As the cost of sequencing decreases, these assays will become increasingly accessible.

Considering the importance of the environment in the development of lung disease, it is somewhat surprising that more attention has not been devoted to epigenetic mechanisms that lead to acute and chronic forms of lung disease. Epigenetic mechanisms (silencing of tumor suppressor genes) and patterns (hypomethylated DNA) have been associated with a number of tumors. In fact, it has been reported that the methylation pattern of six genes is associated with the development of lung cancer.⁵⁷ However, research is just beginning to emerge demonstrating the relevance of epigenetic changes to nonmalignant forms of lung disease. Emerging findings in pulmonary fibrosis suggest that DNA methylation is markedly altered in lung tissue from patients with *idiopathic pulmonary fibrosis* (IPF).⁵⁸ In humans, bronchial biopsy specimens and alveolar macrophages have increased histone acetyltransferase activity and reduced histone deacetylase activity.^{59–61} These consequent increases in histone acetylation enhance gene transcription and are thought to be important in the transcriptional regulation of inflammatory mediators in airway diseases. In fact, steroid-treated asthmatic patients have reduced histone acetyltransferase and increased histone deacetylase activity, presumably resulting in less airway inflammation.⁶¹ In murine studies, methylation has been shown to alter the expression and activity of lineage-specific transcription factors that affect the maturation of naive T cells.^{62–64} These results suggest that a hypomethylated state results in a type 1 T helper phenotype, whereas a hypermethylated state results in a type 2 T helper phenotype. Because cigarette smoke, vitamin supplementation, and other environmental exposures can alter the epigenetic marks along the human genome, studying the importance of changes in DNA methylation, expression of noncoding RNAs, and structural changes in amino acid residues of histones should help us to understand the fundamental mechanisms associated with the etiology and progression of several types of lung disease.

Moreover, the epigenome can be modified by a variety of drugs. Compounds that alter DNA methylation and the amino acid residues on histones are most actively being investigated among patients with cancer. Two DNA methylation inhibitors, 5-aza-deoxycytidine and 5-azacytidine, have recently been approved by the U.S. Food and Drug Administration for the treatment of myelodysplastic syndrome, a preleukemic disease. Compounds that inhibit histone deacetylase have proapoptotic and antitumor properties and are undergoing Phase I trials. Suberoylanilide hydroxamic acid, a histone deacetylase inhibitor, has been approved for the treatment of T-cell cutaneous lymphoma. Interestingly, trichostatin A, another histone deacetylase inhibitor, has been shown to decrease ovalbumin-induced allergic airway disease in a murine model of asthma.⁶⁵ As we begin to understand the role of epigenetic mechanisms

in the development of lung disease, it will become much more obvious how we can modify these mechanisms therapeutically to reduce the burden of lung disease among our patients.

APPLICATION TO PULMONARY DISEASES

ASTHMA

To date there have been reports of positive associations between variants in over 100 genes and asthma phenotypes (e.g., serum immunoglobulin E levels) based on candidate gene, linkage region, and GWAS.⁶⁶ Although there are hundreds of genetic association studies for asthma, many studies suffer from the methodologic problems discussed earlier, and most of the findings have not been adequately replicated. With regard to many genes “replicated” in additional association studies, careful review finds a substantial number of negative studies for all of them, which is likely due to several factors, including population differences, false-positive initial reports, and inadequately powered replication studies. Space constraints do not allow us to cover all of the potential asthma susceptibility genetic variants identified to date, but we review some genes of particular interest with an emphasis on the methodology used to identify the genetic variants and the biologic pathways implicated.

Several potential asthma susceptibility genes have been identified using a positional-cloning approach.^{25-28,67-71} An example of one gene with substantial additional evidence for relevance to asthma susceptibility is G protein–coupled receptor (*GPR154*, also known as *NPSR1*) on chromosome 7p.²⁸ The investigators provided adequate functional data on *GPR154* by showing not only that the mouse orthologue of *GPR154* (*Grpa*) is up-regulated in murine lung after ovalbumin challenge in sensitized mice, but also that in humans *GPR154* encodes protein isoforms that are produced in distinct patterns by bronchial epithelial cells and smooth muscle cells in asthmatic and healthy individuals.

Since the first bronchial asthma GWAS was published in 2007,¹¹ over 30 GWAS have been published for asthma or asthma-related phenotypes. In that first study, *ORMDL3* (a gene involved in the endoplasmic reticulum found to regulate sphingolipid synthesis) on chromosome 17q21 was identified, and the association finding at 17q21 has been confirmed by others.⁷²⁻⁷⁵ However, many of the subsequent GWAS were underpowered for modest effects and failed to find significant associations that could be replicated. However, a few large GWAS studies^{74,75} have provided strong evidence, via meta-analysis and replication, for variants in a number of genes being associated with asthma. Importantly, four of these loci show evidence for association across European American, African American or African Caribbean, and Latino ancestries: chromosome 17q21, *interleukin-1* (IL-1) receptor-like 1 (*IL1RL1*), thymic stromal lymphopoietin (*TSLP*), and IL-33 (*IL33*). *IL1RL1*, *TSLP*, and *IL33* are all implicated in type 2 T helper cell–mediated immune responses, making them strong biologic candidates for asthma susceptibility.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic obstructive pulmonary disease (COPD) is characterized by incompletely reversible airflow obstruction and excess mucus production in the airways. In the United States, COPD affects 16 million individuals, is the fourth leading cause of death, and is the only one among the leading causes of death to be increasing in prevalence.⁷⁶ The role of genetic predisposition in the pathogenesis of COPD had been overlooked until recently, and yet there are intriguing features in this disease to suggest gene–environment interactions. First, the Framingham study demonstrated that longitudinal decline in lung function is inherited with a heritability of approximately 20%, which increases substantially when the subjects were stratified according to smoking status.⁷⁷ Environmental exposures such as smoking and pollution have been implicated in the pathogenesis of COPD since the 1960s, yet “only” 10% to 20% of smokers develop COPD symptoms, further indicating that a susceptibility factor may exist in some individuals. Alpha₁-antitrypsin is a prototypical susceptibility gene that is associated with increased rates of COPD development in active smokers. Recent studies have also implicated alpha₁-antitrypsin in the decline in pulmonary function observed in passive smoke exposure and occupational exposures in susceptible individuals with severely or moderately decreased levels. Furthermore, although traditionally emphysema and chronic bronchitis are considered to be clinically distinct chronic obstructive diseases, in practice there is a substantial gray zone between “pure” irreversible airway obstruction (i.e., COPD) and “pure” reversible obstruction (i.e., asthma). Many physicians are therefore now suspecting that asthma and COPD may be sharing common characteristics and genetic background (the so-called Dutch hypothesis). However, the GWAS to date have not supported that hypothesis. GWAS have identified variants in several genes associated with COPD, but the genes do not overlap with the replicated signals found to date for asthma. There may instead be distinct genetic risk factors for COPD–asthma overlap.^{77a} The first GWAS for COPD⁷⁸ identified a region on chromosome 15q25 containing genes in the aminoglycoside phosphotransferase domain containing 1 (*AGPHD1*) and the nicotinic acetylcholine receptors (*CHRNA3/5*), which are also associated with smoking intensity. That study also identified hedgehog-interacting protein gene (*HHIP*), which has been replicated in other studies of COPD^{79,80} and is associated with pulmonary function.⁸¹ Other GWAS have identified family with sequence similarity 13, member A (*FAM13A*)⁷⁹ and a locus on chromosome 19q13⁸²; the functional relevance of these genes in relationship to COPD is not yet understood. Additional insight into the genetics of COPD might come from the genetics of primary ciliary dyskinesia.^{82a}

ACUTE RESPIRATORY DISTRESS SYNDROME

Acute lung injury (ALI) leading to *acute respiratory distress syndrome* (ARDS) is a common complication of systemic inflammation and sepsis, seen in approximately 50% of such patients. The mortality of ARDS remains high at about 30% to 40%, despite recent advances in mechanical ventilation and patient management. The pathogenesis

of ALI/ARDS is thought to derive from the effects of systemic inflammation, cytokine production, and oxidative damage. However, the sporadic (nonfamilial) nature of ARDS hampers genetic analysis of human subjects. Genetic analysis of inbred mouse strains first revealed that ALI susceptibility was strain dependent and therefore may, in part, be genetically determined.⁸³ Human studies identified *angiotensin-converting enzyme (ACE)* as a candidate gene for ARDS susceptibility.⁸⁴ Subsequent animal studies verified the role of ACE in ARDS susceptibility and further showed that ACE2, an ACE isoform that metabolizes the ACE product angiotensin II, is protective against ARDS.⁸⁵ This was the first set of studies to show a link and a mechanism for genetic susceptibility and ARDS pathogenesis. Subsequently, variants in over 25 genes have been found to be associated with either the development or outcome of ALI/ARDS,⁸⁶ and, not surprisingly, these candidate genes are involved in inflammation, innate immunity, oxidative stress, apoptosis, and coagulation. A number of candidate genes, mostly from the inflammation and coagulation pathways, were identified: IL-1 β , IL-6, tissue factor, plasminogen activator inhibitor 1, and chemokine receptors were the most abundantly up-regulated proteins.⁸⁷ Surfactant protein B polymorphisms have also been associated with increased susceptibility to ARDS.⁸⁸ Surfactant protein B has not been used therapeutically in adults with ARDS; however, a recent study in infants and children with ARDS showed significant improvement in survival with a surfactant that contained surfactant protein B.⁸⁹ The only genome-wide association study in ALI that has been published identified a region on chromosome 11 (11q13.3) that contained a cell adhesion gene, *PPFIA1*.⁹⁰ Although the genetic risks for ALI/ARDS are continuing to emerge, attention is beginning to focus on disease prevention by identifying those at risk and using the genetic findings to direct therapy in this severe form of ALI.⁹¹ However, results remain preliminary, and susceptibility testing for ALI/ARDS will require more definitive research findings.

LUNG CANCER

Lung cancer is now the most common cause of cancer-related deaths in the United States, and yet no more than 100 years ago lung cancer was quite rare. The rise in lung cancer incidence demonstrates the effects of changing environmental exposures on human disease. Inhalation of environmental carcinogens causes the vast majority of lung cancer cases. Cigarette smoke dominates this list. Since at least the 1950s, it has been recognized that cigarette smoking causes most lung cancer cases. However, only a minority of smokers develop lung cancer, again suggesting the role of susceptibility in lung cancer pathogenesis. Unfortunately, cigarette smoke contains more than 4000 chemicals, a fact that makes the search for a single susceptibility factor much more difficult. Investigators have focused on specific classes of tobacco compounds that are known carcinogens, such as the polycyclic aromatic hydrocarbons. These are nontoxic in themselves but are metabolized in the body by enzymes such as CYP1A1 into DNA-binding diol-epoxides. Several studies from Japan have shown a significant association of high-activity CYP1A1 variants with the development of lung cancer.⁹² On the other hand, the main

polycyclic aromatic hydrocarbon–detoxifying enzymes are the glutathione S-transferases GSTM1 and GSTP1. Polymorphisms in these enzymes that lead to reduced activity have also been linked to lung cancer susceptibility.⁹³ Variants in other genes known to metabolize inhaled carcinogens (*NAT1*, *NAT2*, *MEH*, *NQO1*, and *MPO*) are reported to be associated with lung cancer.⁹⁴ The carcinogenic effect of cigarette smoke is thought to rely upon DNA binding and mutations of tumor suppressor genes, such as P53. Polycyclic aromatic hydrocarbon and other smoke constituents like acrolein can bind to so-called mutational hotspots of the P53 gene and induce DNA damage.⁹⁵ Accordingly, the ability of the organism to correct and repair DNA damage is closely linked to cancer susceptibility.^{96,97} For example, a recent analysis of a European cohort of 116 patients with lung cancer showed a significant association between SNPs in the DNA repair enzymes XRCCI and BRCA2 and exposure to urban pollution in the susceptibility to cancer.⁹⁸ Other DNA repair genes associated with the development of lung cancer include *ERCC2/XPD*, *ERCC1/XPF*, *XPA*, *XPC*, *ERCC5/XPG*, *OGG1*, *APE*, and *XRCC3*.⁹⁴

Genomic medicine not only is helpful in detecting genes associated with the development of lung cancer, but can also be used to guide therapy⁹⁹ and to determine the prognosis of the patient^{100,101} (Fig. 3-3). Indeed, lung cancers can now be categorized based on their gene expression profile.^{100,102,103} Furthermore, somatic mutations in proto-oncogenes such as *KRAS*, *BRAF*, and *EGFR* have been

Figure 3-3 Evolution of knowledge in non-small-cell lung cancer. Traditionally, non-small-cell lung cancers have been classified according to histological features. More recently, various driver mutations have been associated with these cancers. The mutations are mutually exclusive, except for those in PIK3CA. (From Pao W, Girard N: New driver mutations in non-small-cell lung cancer. *Lancet Oncol* 12:175-180, 2011.)

identified that have become targets of cancer drugs.^{104,104a,104b} Indeed, the most encouraging reports in lung cancer research were the recent findings that certain non-small cell lung cancers harbor mutations in the *epidermal growth factor receptor* (*EGFR*) gene and gain-of-function tyrosine kinase-activating *ALK* gene rearrangements that predict prognosis and response to therapy.¹⁰⁴ These cell lines become malignant through *EGFR*-induced inhibition of apoptosis but simultaneously become extremely sensitive to *EGFR* tyrosine kinase inhibitors like gefitinib or erlotinib. Similarly, the lung cancers with *ALK* gene rearrangements show improved progression-free survival with the first-in-class *ALK* tyrosine kinase inhibitor, crizotinib.¹⁰⁵ These are impressive accomplishments of genomic medicine that provided a seamless link between the pathogenesis of lung cancer, the prediction of treatment effect based on genetic cancer characteristics, and the successful application of treatment to patients with lung cancer.

FIBROSING IDIOPATHIC INTERSTITIAL PNEUMONIA

Fibrosing *idiopathic interstitial pneumonia* (IIP) refers to a group of lung diseases that are characterized by progressive scarring of the alveolar interstitium that leads to significant morbidity and mortality. IPF is the most common and severe form of fibrosing IIP; 50,000 individuals are newly diagnosed each year in the United States,¹⁰⁶ and patients with IPF have a median survival of 3 years. There is substantial

evidence for a genetic basis for IPF, including familial aggregation confirmed through studies in twins, siblings raised apart, and multigenerational families.^{107,108,108a} Fibrosing IIP has been associated with several pleiotropic genetic disorders.¹⁰⁸ Rare mutations in the *TERT*, *TERC*, *SFTPC*, and *SFTPA2* genes have been associated with familial interstitial pneumonia (defined as two or more family members with IIP) and IPF,¹⁰⁹⁻¹¹⁴ and a common polymorphism in *TERT* has been associated with IPF.¹¹⁵ However, in aggregate, these mutations account for a small proportion of the population attributable risk for development of IPF. Recently a promoter variant in the *MUC5B* gene (rs35705950) has been found to be present in approximately 50% to 60% of individuals with familial or sporadic forms of IPF and is estimated to increase the risk 6-fold for heterozygotes and 20-fold for homozygotes²⁹ (Fig. 3-4). Independent investigators have verified a similar relationship between the *MUC5B* promoter variant (rs35705950) and IPF,¹¹⁶⁻¹¹⁹ and this effect appears to be present, though less pronounced, among patients with idiopathic nonspecific interstitial pneumonia.¹²⁰ Importantly, the *MUC5B* promoter SNP also appears to be both predictive and prognostic in IPF. In the Framingham population (N = 2639), the *MUC5B* promoter SNP is associated with a threefold to sixfold excess risk per allele for radiographic evidence of interstitial lung disease,¹²¹ suggesting that the *MUC5B* promoter SNP could be used to identify individuals with preclinical forms of IPF. Moreover, in two independent cohorts of patients with IPF, the *MUC5B* promoter polymorphism (rs35705950) is associated with a

Figure 3-4 Genome-wide association (GWA) studies results for pulmonary fibrosis across 439,828 single nucleotide polymorphisms (SNPs) with 1616 cases and 4683 controls under an additive model. GWA studies have become the standard approach for identification of common sequence alleles associated with complex diseases and are typically conducted in two phases: discovery across the genome and replication of a smaller set of SNPs in independent samples. For the pulmonary fibrosis example, the results of the first discovery phase are shown in this “Manhattan plot.” In the second phase, SNPs above the red line that were genome-wide significant at $P < 5 \times 10^{-8}$ and the SNPs between the red and blue lines (corresponding to $5 \times 10^{-8} < P < 0.0001$) were selected for follow-up in 876 cases and 1890 controls. After considering both phases of the study, seven novel loci for pulmonary fibrosis were identified. (From Fingerlin TE, Murphy E, Zhang W, et al: Genome-wide association study identifies multiple susceptibility loci for pulmonary fibrosis. *Nat Genet* 45:613–620, 2013. Epub 2013;April 16. Reprinted with permission from Nature Genetics).

twofold improved survival per allele.¹²² However, the *MUC5B* variant is observed in approximately 19% of unaffected individuals, and approximately one third of individuals with IPF do not have any identifiable genetic risk factors for disease, suggesting that other genetic variants and/or environmental exposures contribute to disease risk alone or in combination with the *MUC5B* variant. A recent genome-wide association study has provided additional understanding of the genetic features of IPF by confirming *TERT* (5p15), *MUC5B* (11p15), and the chromosome 3q26 region near *TERC* and identifying seven novel risk loci.¹¹⁹ The novel loci include *FAM13A* (4q22), *DSP* (6p24), *OBFC1* (10q24), *ATP11A* (13q34), *DPP9* (19p13), and chromosomal regions 7q22 and 15q14-15. Further characterizing these IPF-associated loci will provide important targets for functional studies that will ultimately allow for the development of new prevention and treatment strategies.¹²³

THE PATH FORWARD

Although the Human Genome Project has successfully mapped the human genome and has developed innovative technology for genomic studies, we remain limited in how this information can be used to improve clinical medicine and public health. This limitation arises from the simple fact that genetics is not the sole determinant of health or disease. In fact, although an emerging consensus suggests that many of the complex and prevalent diseases that humans develop as a result of multiple biologically unique gene-gene and gene-environment interactions, even this conceptual framework is limited. The development of disease in humans, environmental and otherwise, is simply far more complex. Environmental exposures affect those that are vulnerable temporally (age), spatially (geographically), and by unique circumstance (comorbid disease, nutritional status, economic status, race, and genetics). Even this paradigm fails to address the complex interaction of endogenous and exogenous risks that ultimately interact to cause disease. Moreover, diseases are not usually single entities; rather, most diseases represent several or many specific pathophysiologic processes that can be fully understood only by focusing on the genetic and environmental contributions to etiology and pathogenesis. Environmental health research and genomic research are logical, even necessary, partners. Ultimately, the discoveries that are made in environmental genomics will lead to better diagnosis, treatment, and prevention of these common, complex human diseases.

Key Points

- Heritability is a measure of the contribution of genetic variation to variation in a phenotype.
- Complex genetic disorders account for the majority of lung diseases and are caused by multiple genetic variations and multiple environmental factors.
- The human genome comprises approximately 3 billion base pairs. There are approximately 12 million single nucleotide polymorphisms in the human genome.
- Linkage analysis is a group of analysis methods to analyze the distribution of DNA markers within

families to determine if there is a relationship between a particular region of the genome and a phenotype of interest.

- Genome-wide association studies have emerged as the most commonly used study design to find disease genes in complex disorders.
- Epigenetics is the study of changes in gene transcription that are dependent on the molecules that bind to DNA rather than on the base pair sequence of DNA. This includes both heritable changes in gene expression and stable, long-term alterations in the transcriptional potential of a cell or tissue that are not necessarily heritable.
- Asthma is a heritable disorder, but the genetics are very complex, with almost every chromosome demonstrating linkage and over 100 genes found to be associated with the development of asthma, which explain less than 10% of the inheritance of this disease.
- COPD has many intriguing features to suggest gene-environment interactions.
- Lung cancer develops in only a minority of smokers, and thus genetic and epigenetic mechanisms need to be considered. Non-small cell lung cancers harbor mutations in the epidermal growth factor receptor and gain-of-function tyrosine kinase-activating *ALK* gene rearrangements that predict prognosis and response to therapy.
- Interstitial lung disease is caused by environmental and genetic factors. Mutations in surfactant protein C and the telomerase genes have been shown to enhance the risk for developing this disorder. A common polymorphism in the promoter of the *MUC5B* gene is strongly associated with the development of familial and sporadic forms of idiopathic pulmonary fibrosis. Recently seven novel loci have been found to be associated with the development of pulmonary fibrosis.

Oxygen Sensing

INTRODUCTION

This first chapter in the section on respiratory physiology is devoted to the primary function of the lung: gas exchange. In addition, the principles of ventilation and blood flow that underlie gas exchange are reviewed. Although the lung has other functions, such as metabolizing some compounds, filtering unwanted materials from the circulation, and acting as a reservoir for blood, gas exchange is its chief function. Respiratory diseases frequently interfere with ventilation, blood flow, and gas exchange and may ultimately lead to respiratory failure and death.

VENTILATION

The anatomy of the airways and the alveolar region of the lung is discussed in Chapter 1. There we saw that the airways consist of a series of branching tubes that become narrower, shorter, and more numerous as they penetrate deeper into the lung. This process continues down to the terminal bronchioles, which are the smallest airways without alveoli. All these bronchi make up the *conducting airways*. Their function is to channel inspired gas to the gas-exchanging regions of the lung. Because the conducting

airways contain no alveoli and therefore take no part in gas exchange, they constitute the *anatomic dead space*.

Each terminal bronchiole subtends a respiratory unit, or *acinus*. The terminal bronchioles divide into respiratory bronchioles that have occasional alveoli budding from their wall, and these then transition to the alveolar ducts, structures that are completely lined with alveoli. This alveolated region of the lung where gas exchange takes place is known as the *respiratory zone*. The distance from the terminal bronchiole to the most distal alveolus is only approximately 5 mm, but the respiratory zone makes up most of the lung in terms of gas volume (some 2 to 3 L).

The morphologic characteristics of the human airways were greatly clarified by Weibel.¹ He measured the number, length, width, and branching angles of the airways, and he proposed models that, although they are idealized, make pressure-flow and other analyses much more tractable.

The most commonly used Weibel model is the so-called model A, shown in [Figure 4-1](#). Note that the first 16 generations (Z) make up the conducting airways ending in the terminal bronchioles. The next three generations constitute the respiratory bronchioles, in which the degree of alveolation steadily increases. This is called the *transitional zone* because the nonalveolated regions of the respiratory bronchioles do not have a respiratory function. Finally, there are

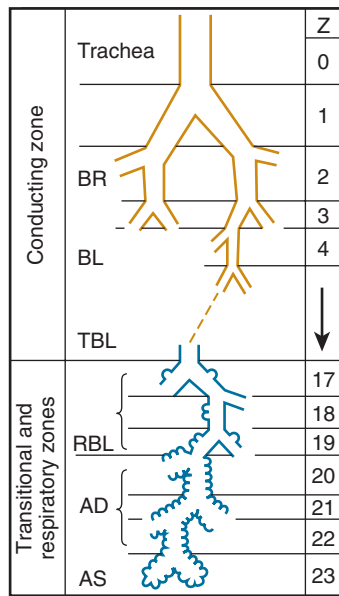

Figure 4-1 Idealization of the human airways according to Weibel's model A. AD, alveolar duct; AS, alveolar sac; BL, bronchiole; BR, bronchus; RBL, respiratory bronchiole; TBL, terminal bronchiole; Z, airway generation. Note that the RBL, AD, and AS make up the transitional and respiratory zones. (Redrawn from Weibel ER: *Morphometry of the human lung*, Berlin, 1963, Springer-Verlag.)

Figure 4-2 Diagram showing the extremely rapid increase in total cross-sectional area of the airways in the respiratory (Resp.) zone as predicted from the Weibel model in Figure 4-1. (Redrawn from West JB: *Respiratory physiology—the essentials*, ed 9, Baltimore, 2012, Lippincott Williams & Wilkins.)

three generations of alveolar ducts and one generation of alveolar sacs. These last four generations constitute the true *respiratory zone*.

Other models of the airways have been proposed.² However, the Weibel model has been of great value to respiratory physiology, and an example of its use is shown in Figure 4-2. Here the model clarifies the nature of gas flow

in all generations of the airways in the lung. Figure 4-2 shows that, if the total cross-sectional area of the airways of each generation is calculated, there is relatively little change in area until we approach generation 16, that is, the terminal bronchioles. However, near this level, the cross-sectional area increases very rapidly. This has led some physiologists to suggest that the shape of the combined airways is similar to a trumpet or even a thumbtack!

The result of this rapid change in area is that the mode of gas flow changes in the region of the terminal bronchioles. Proximal to this point, flow is convective, or “bulk,” that is, similar to the sort of flow that results when beer is poured out of a pitcher. However, when the gas reaches the region approximating the level of the terminal bronchioles, its forward velocity decreases dramatically because of the very sudden increase in cross-sectional area. As a consequence, diffusion begins to take over as the dominant mode of gas transport. Naturally, there is no sharp transition; flow changes gradually from primarily convective to primarily diffusive in the general vicinity of generation 16.

One implication of this change in mode of flow is that many aerosol particles penetrate to the region of the terminal bronchioles by convective flow, but they do not penetrate further because of their large mass and resulting low diffusion rate. Thus sedimentation of these particles is heavy in the region of the terminal respiratory bronchioles. This is one reason why this region of the lung is particularly vulnerable to the effects of particulate air pollutants.

Another implication of this dichotomously branching airway tree is that the greater the number of branch points, the greater the potential for nonuniform distribution of airflow among the distal airways and alveoli. In addition, repeated, possibly minor, differences in flow distribution at each branch point will give rise to spatial correlation of flow; in other words, neighboring regions will tend to have more similar flows than regions located far apart, other factors being equal.

LUNG VOLUMES

Figure 4-3 shows the major divisions of lung volume. *Total lung capacity* is the volume of gas contained in the lungs at maximal inspiration. The *vital capacity* is the volume of gas that can be exhaled by a maximal expiration from total lung capacity. The volume remaining in the lung after maximal expiration is the *residual volume* (RV). *Tidal volume* refers to the normal respiratory volume excursion. The lung volume at the end of a normal expiration is the *functional residual capacity* (FRC). The diagram also indicates the *inspiratory reserve volume* and the *expiratory reserve volume*. These volumes change in characteristic directions with different respiratory diseases, and so their measurement becomes important. Indeed, they have for years formed the basis for diagnosis and monitoring of chronic diseases such as *chronic obstructive pulmonary disease* (COPD) and lung fibrosis (see Chapter 25).

Functional Residual Capacity, Residual Volume, and Total Lung Capacity

These three volumes cannot be measured with a spirometer (a device that measures the volume of air being exhaled or

Figure 4-3 Major divisions of lung volumes. Values are illustrative only; there is considerable normal variation. ERV, expiratory reserve volume; IRV, inspiratory reserve volume. (Modified from West JB: *Respiratory physiology—the essentials*, ed 9, Baltimore, 2012, Lippincott Williams & Wilkins.)

inhaled) because there is no way of knowing the volume remaining in the lung after a maximal expiration (i.e., the RV). However, if any one of these three volumes is measured by an independent method, the other two can be derived by spirometry.

The FRC can be measured conveniently by helium dilution in a closed circuit. The subject is connected to a spirometer of known volume that contains a known concentration of helium (a very insoluble gas) and then rebreathes until the helium concentration in the spirometer and in the lungs is the same. The exhaled carbon dioxide is absorbed with soda lime, and oxygen is added to maintain a constant total volume. After equilibration, the total amount of helium is assumed to be unchanged because so little of it is removed by the blood because of its very low solubility. The FRC can then be derived from the following equation that expresses this conservation of mass principle:

$$C_1 \times V_1 = C_2 \times (V_1 + V_2) \quad [1]$$

where C_1 and C_2 are the helium concentrations before and after equilibration, V_1 is the volume of the spirometer, and V_2 is the volume of the lung. If the subject is switched into the equipment when at FRC, V_2 gives that volume.

Another common way of measuring the FRC is with a body plethysmograph. This is a large airtight box in which the subject sits. At the end of a normal expiration, a shutter closes the mouthpiece, and the subject is asked to make respiratory efforts. As the subject tries to inhale, the gas in the lungs expands, lung volume increases slightly, and the pressure in the box rises slightly because its gas volume decreases. Boyle's law (pressure times volume is constant at constant temperature) can then be used to calculate the change of volume of the plethysmograph. The equation is $P_1V_1 = P_2(V_1 - \Delta V)$, where P_1 and P_2 are the box pressures before and after the inspiratory effort, V_1 is the preinspiratory box volume, and ΔV is the change in the volume of the box (or lung). If mouth pressure is also measured during the respiratory efforts, Boyle's law can also be applied to the

lung and FRC can be derived. The equation here is $P_3V_2 = P_4(V_2 + \Delta V)$, where P_3 and P_4 are the mouth pressures before and after the inspiratory effort, and V_2 is the FRC. Because this is the only unknown (ΔV was measured previously), V_2 can be calculated.

In patients with lung disease the FRC measured by helium dilution may be substantially less than that measured by body plethysmography. The reason is that the body plethysmograph measures the total volume of gas in the lung, including any that is trapped behind closed airways (i.e., unventilated regions that contain gas). By contrast, the helium dilution method measures only ventilated lung regions. In young normal subjects, these volumes are virtually identical, but they may be considerably different in patients with severe lung disease. Also in these patients, regions that are poorly ventilated reduce the overall speed of equilibration of helium, which will lead to volume underestimation if rebreathing is stopped too soon.

TOTAL AND ALVEOLAR VENTILATION

Total Ventilation

Total ventilation, also called minute ventilation, is the total volume of gas exhaled per minute. It is equal to the tidal volume times the respiratory frequency. The volume of inhaled air is slightly greater than the exhaled volume because more oxygen is inhaled than carbon dioxide is exhaled, but the difference is usually less than 1%.

Alveolar ventilation is the amount of fresh inspired air (non-dead space gas) that enters the alveoli per minute and is therefore available for gas exchange. Strictly, the alveolar ventilation is also measured during expiration, but the inhaled and exhaled volumes are almost the same.

Alveolar Ventilation

Because the tidal volume (V_T) is made up of the dead space volume (V_D) and the volume of gas entering (or coming

from) the alveoli (VA), the alveolar ventilation can be measured from the following equations:

$$V_T = V_D + V_A \quad [2]$$

Multiplying by respiratory frequency gives

$$\dot{V}_E = \dot{V}_D + \dot{V}_A \quad [3]$$

where \dot{V}_A is the alveolar ventilation, and \dot{V}_E and \dot{V}_D are the expired total ventilation and dead space ventilation, respectively.

Therefore,

$$\dot{V}_A = \dot{V}_E - \dot{V}_D \quad [4]$$

A difficulty with this method is that the anatomic dead space is not easy to measure, although a value for it can be assumed with little error. One milliliter per pound of body weight is a common assumption. This approximation will overestimate dead space in obese subjects and so should be applied using ideal body weight for height.

Another way of measuring alveolar ventilation in normal subjects is to use the *alveolar ventilation equation*, which expresses mass conservation of carbon dioxide by defining *carbon dioxide production* (\dot{V}_{CO_2}) as the product of *alveolar ventilation* (\dot{V}_A) and *fractional alveolar concentration of carbon dioxide* (F_{ACO_2}). Because concentration is proportional to partial pressure, the relationship can be written as:

$$\dot{V}_{CO_2} = \dot{V}_A \times F_{ACO_2} = \dot{V}_A \times P_{ACO_2} / K \quad [5]$$

This can then be rearranged as follows:

$$\dot{V}_A = \frac{\dot{V}_{CO_2}}{P_{ACO_2}} \times K \quad [6]$$

where \dot{V}_{CO_2} is the volume of carbon dioxide exhaled per unit time, P_{ACO_2} is the alveolar PCO_2 , and K is a constant (0.863 when \dot{V}_A is expressed in LBTSP/min, \dot{V}_{CO_2} in mlSTPD/min, and P_{ACO_2} in mm Hg). In patients with normal lungs, the PCO_2 of alveolar gas and that of arterial blood are virtually identical. Therefore the arterial PCO_2 can be used to determine alveolar ventilation from Equation 6. The equation then becomes

$$\dot{V}_A = \frac{\dot{V}_{CO_2}}{P_{ACO_2}} \times K \quad [7]$$

This equation is often used in patients with lung disease, but the value then obtained is the “effective” alveolar ventilation. This is not the same as the alveolar ventilation as defined in Equation 4. Because patients with lung disease must increase their total ventilation to overcome the inefficiency of gas exchange caused by ventilation-perfusion inequality just to keep arterial PCO_2 normal, \dot{V}_A from Equation 7 will be less than that from Equation 4.

ANATOMIC DEAD SPACE

The anatomic dead space is the gas volume contained within the conducting airways. The normal value is in the range of 130 to 180 mL and depends on the size and posture of the subject. The value increases slightly with large inspirations because the radial traction exerted on the bronchi by the surrounding lung parenchyma increases their size. Anatomic dead space can be measured by Fowler’s method,³ in which a single breath of oxygen is inhaled

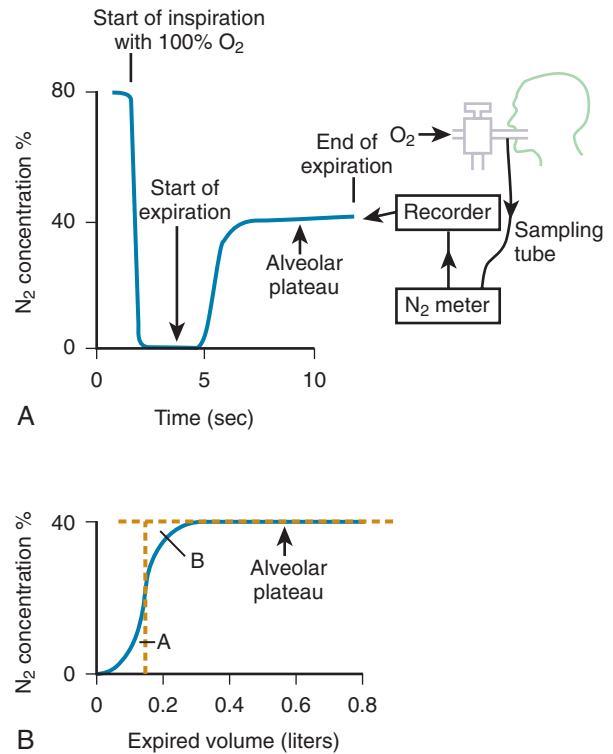

Figure 4-4 Fowler’s method of measuring the anatomic dead space with a rapid N_2 analyzer. A shows that, following a test inspiration of 100% O_2 , the N_2 concentration rises during expiration to an almost level “plateau” representing pure alveolar gas. B, N_2 concentration is plotted against expired volume, and the dead space is the volume up to the vertical dashed line, which makes the areas A and B equal. (Redrawn from West JB: *Respiratory physiology—the essentials*, ed 9, Baltimore, 2012, Lippincott Williams & Wilkins.)

and the concentration of nitrogen in the subsequent expiration is analyzed, as shown in Figure 4-4.

PHYSIOLOGIC DEAD SPACE

Unlike anatomic dead space, which is determined by the anatomy of the airways, physiologic dead space is a functional measurement based on the ability of the lungs to eliminate carbon dioxide. It is defined by the Bohr equation:

$$\frac{V_D}{V_T} = \frac{P_{ACO_2} - P_{ECO_2}}{P_{ACO_2}} \quad [8]$$

where A and E refer to alveolar and mixed expired gas, respectively. In subjects with normal lungs, the PCO_2 of alveolar gas and that of arterial blood are virtually the same, so that the equation is often written

$$\frac{V_D}{V_T} = \frac{P_{ACO_2} - P_{ECO_2}}{P_{aCO_2}} \quad [9]$$

Physiologic dead space includes and is very nearly the same as anatomic dead space when the lung is normal. However, in the presence of ventilation-perfusion inequality (i.e., when the ratio of local ventilation to local blood flow is not everywhere the same), physiologic dead space is increased, chiefly because of the ventilation going to lung units with abnormally high ventilation-perfusion ratios. Indeed, the physiologic dead space is often reported as one of the indices

of the degree of mismatching of ventilation and blood flow within the lung. It is important to understand that, when dead space is expressed as a fraction of tidal volume as in Equation 9, the result is sensitive to tidal volume; for example, a dead space of 150 mL is 30% of a 500-mL tidal volume but only 15% of a 1000-mL tidal volume.

INEQUALITY OF VENTILATION

Not all the alveoli are equally ventilated, even in the normal lung. There are several reasons for this, related both to gravitational (topographic) and to nongravitational influences on gas distribution.

Topographic Inequality

Regional differences in ventilation can be measured by having the patient inspire a radioactive gas such as xenon (^{133}mXe). In one technique the patient inhales a single breath of gas, and its concentration is detected by a radiation camera placed behind the chest. An additional measurement is made after the patient has rebreathed long enough to allow the xenon to equilibrate throughout the different regions of the lungs, thus reflecting regional lung volumes. By comparing the first and the second measurements, the ventilation per unit alveolar volume can be obtained.

Measurements in upright normal subjects show that the ventilation per unit volume of the lung is greatest near the base of the lung and becomes progressively smaller toward the apex. When the subject lies supine, this difference becomes much less, but the ventilation of the lowermost (posterior) lung exceeds that of the uppermost (anterior). In the lateral decubitus position, again, the dependent lung is better ventilated. (These results refer to an inspiration from FRC.)

An explanation of this topographic inequality of ventilation is shown in Figure 4-5A, which depicts conditions at FRC.⁴ The intrapleural pressure is less negative at the bottom than at the top of the lung. This pattern can be attributed to the weight of the lung, which requires a larger pressure below the lung than above it to balance the downward-acting weight forces.⁵ There are two consequences of this lower expanding pressure on the base of the lung. First, the resting volume of the basal alveoli is smaller, as shown by the pressure-volume curve. Second, the change in volume

for a given change in intrapleural pressure is greater because the alveoli are operating on a steeper part of the pressure-volume curve. Thus the ventilation (change in volume per unit resting volume) is greater at the base than the apex. However, if a normal subject makes a small inspiration from RV (rather than from FRC), an interesting change in the distribution of ventilation is seen. The major share of the ventilation goes to the apex of the upright lung, whereas the base is very poorly ventilated. Figure 4-5B shows why a different pattern is seen in this case. Now the intrapleural pressures are less negative, and the pressure at the base of the lung actually exceeds atmospheric pressure. For a small fall in intrapleural pressure, no gas will enter the extreme base of the lung, and only the apex will be ventilated. Thus the normal pattern of uneven ventilation is reversed in this early phase of inhalation.

Hyperpolarized helium and xenon magnetic resonance imaging have been used to measure regional ventilation and give similar results, although there are small differences in results obtained with the two gases for reasons that remain to be determined.^{6,7}

Airway Closure

At RV the compressed region of the lung at the base in Figure 4-5B does not have all its gas squeezed out because small airways, probably in the region of the respiratory bronchioles, close first and trap gas in the distal alveoli. This is known as *airway closure*. In young normal subjects, airways close only at lung volumes below FRC. However, in older normal subjects, the volume at which the basal airways close (*closing volume*) increases with age and may encroach on the FRC. The reason for this increase is that the aging lung loses some of its elastic recoil and the intrapleural pressures therefore become less negative, thus approaching the situation shown in Figure 4-5B. Under these conditions, basal regions of the lung may be ventilated only intermittently, with resulting defective gas exchange. A similar situation frequently develops in patients with COPD in whom lung elastic recoil may be reduced.

Nontopographic Inequality

In addition to the topographic inequality of ventilation caused by gravitational factors (see Fig. 4-5), nongravitational mechanisms also exist. This is proved by the fact that

Figure 4-5 The topographic inequality of ventilation down the lung. A, An inspiration from functional residual capacity. B, The situation at very low lung volumes (see text for details). (Redrawn from West JB: *Respiratory physiology—the essentials*, ed 9, Baltimore, 2012, Lippincott Williams & Wilkins.)

even astronauts in space beyond the reach of gravity show uneven ventilation by both the single-breath and the multi-breath nitrogen washout methods.^{8,9} These methods are described in Chapter 25. Such findings have been confirmed by studies in which inspired gas is labeled by small particles. Such studies show considerable variability in ventilation at a given horizontal level.⁶

Several factors are responsible for uneven ventilation in the distal, smaller regions of the lung. One of these is the existence of uneven time constants.¹⁰ The *time constant* of a region of lung is given by the product of its resistance and compliance (analogous to the time constant in electrical circuits, which is the product of electrical resistance and capacitance). Lung units with different time constants inflate and deflate at different flow rates. Depending on the breathing frequency, a unit with a large time constant does not complete its filling before expiration begins and therefore is poorly ventilated; the faster the frequency, the less time for ventilation. In contrast, a unit with a small time constant, which fills rapidly, may receive a higher proportion of gas from the anatomic dead space, which also reduces its effective alveolar ventilation.

Another cause of uneven ventilation in small lung units is the asymmetry of their structure, which can result in a greater penetration of gas by diffusion into the smaller units than into the larger.¹¹ The resulting somewhat complex behavior is known as diffusion- and convection-dependent inhomogeneity and may play an important role in lung disease.

A further possible reason for uneven ventilation at the level of small lung units is the presence of concentration gradients along the small airways. This is known as *series inequality*. Recall that inspired gas reaches approximately the region of the terminal or respiratory bronchioles by convective flow, but gas flow over the rest of the distance to the alveoli is accomplished principally by diffusion within the airways. If there is abnormal dilatation of an airway, the diffusion process may not be complete within the breathing cycle, and the distal alveoli will be less well ventilated than the proximal alveoli.

BLOOD FLOW

Blood flow is as important for gas exchange as is ventilation. This has not always been appreciated, partly because the process of ventilation is more obvious, especially in the dyspneic patient, and is more accessible to measurement. Much has been learned about the pulmonary circulation in the past few years, especially its metabolic functions. The anatomy and function of the pulmonary circulation is also described in Chapters 1 and 6.

PRESSURES OF THE PULMONARY CIRCULATION

The pressures in the pulmonary circulation are very low compared with those in the systemic circulation, and this feature is responsible for much of its special behavior. The normal pressures in the human pulmonary artery are typically approximately 25 mm Hg systolic, 8 mm Hg diastolic, and 15 mm Hg mean. Normal mean systemic arterial pressure is approximately 100 mm Hg, which is six times higher

than that in the pulmonary circulation. The evolutionary force to keep the pressures in the pulmonary circulation so low is the mechanical vulnerability of the extremely thin blood-gas barrier. Higher pressures in the pulmonary capillaries would cause stress failure of the capillary wall.¹²

Pressure Inside Blood Vessels

Because the pulmonary arterial pressure is so low, hydrostatic effects within the pulmonary circulation are very important. The adult upright human lung is some 30 cm high, giving a hydrostatic difference in pressure of 30 cm blood between the extreme apex and the base, which is equivalent to approximately 23 mm Hg. As a result, there are very substantial differences in flow within the small pulmonary arteries and the capillaries between the top and bottom of the upright lung. This topic is discussed further in the section on the distribution of pulmonary blood flow.

Various techniques have been used to determine the pattern of pressure drop along the pulmonary blood vessels. These include measurement of the transudation pressure on the pleural surface of isolated lung, measurement of the pressure transient resulting from the injection of a slug of low- or high-viscosity blood into the pulmonary artery,¹³ and direct puncture of different-sized vessels along with direct measurement of hydrostatic pressure.¹⁴ The direct puncture measurements indicate that much of the normal pressure drop in the pulmonary circulation probably takes place in the pulmonary capillaries, and that the mean capillary pressure is approximately halfway between that in the pulmonary artery and that in the pulmonary vein (Fig. 4-6). This distribution of the pressure drop is consistent with the main function of the pulmonary circulation, which is to expose as large an area of blood as possible to the alveolar gas.

The distribution of pressure along the pulmonary blood vessels depends on lung volume. At low states of lung inflation, the resistance of the extra-alveolar vessels (see next section) increases, and more pressure drop then takes place across the pulmonary arteries and veins. By contrast, there is evidence that, at very high states of lung inflation, the

Figure 4-6 Pressure drop along the pulmonary circulation as determined by direct puncture of vessels. PA, pulmonary artery; PV, pulmonary vein. (Redrawn from Bhattacharya J, Nanjo S, Staub NC: Factors affecting lung microvascular pressure. *Ann N Y Acad Sci* 384:107–114, 1982.)

resistance of the capillary bed is increased, and therefore there will be an additional pressure drop in the capillaries.

The pressures in the pulmonary circulation are highly pulsatile; indeed, if we take the normal systolic and diastolic pressures in the main pulmonary artery as 25 and 8 mm Hg, respectively, this represents a much greater proportional change than the systolic-diastolic difference in systemic arteries (120 and 80 mm Hg, respectively). There is good evidence that the pulsatility of pressure, and therefore flow, extends to the pulmonary capillaries.¹⁵

Pressures Outside Blood Vessels

Some pulmonary blood vessels are exposed to alveolar pressure (or very nearly), whereas others are outside the influence of alveolar pressure but are very sensitive to the state of lung inflation. These two types of vessels are known as alveolar and extra-alveolar, respectively (Fig. 4-7).

The alveolar vessels are largely capillaries that course through the alveolar walls. The pressure to which they are exposed is very nearly alveolar pressure. However, it can be shown that, when the lung is expanded from a very low lung volume, this pericapillary pressure falls below alveolar pressure because of surface tension effects in the alveolar lining layer.¹⁶ By contrast, during deflation from high lung volumes, the pericapillary pressure is very close to alveolar pressure.

Figure 4-7 **A**, Section of lung showing an extra-alveolar vessel (in this case, a small vein) surrounded by alveoli. Note the potential perivascular space. **B**, Diagram of alveolar and extra-alveolar vessels. The alveolar vessels are mainly the capillaries and are exposed to alveolar pressure. The extra-alveolar vessels have their lumina enlarged by the pull of radial traction (outward-oriented arrows) of the surrounding parenchyma. (Modified from *Respiratory physiology—the essentials*, ed 9, Baltimore, 2012, Lippincott Williams & Wilkins.)

The extra-alveolar vessels are not exposed to alveolar pressure. The caliber of these vessels is determined by the radial traction of the surrounding alveolar walls and therefore depends on lung volume. When the lung inflates, the caliber of these vessels increases; when the lung deflates, their caliber decreases because of the elastic tissue in their walls and also because of a small amount of smooth muscle tone. The important point is that extra-alveolar vessel resistance falls with lung inflation, whereas alveolar vessel (capillary) resistance rises with lung inflation.

The small vessels (of approximately 30 μm diameter) in the corners of the alveolar walls behave in a manner that is intermediate between that of the capillaries and the extra-alveolar vessels. These corner vessels can remain open when the capillaries are closed. Indeed, this is the normal appearance in zone 1 lung¹⁷ (see later section on the distribution of blood flow). However, the shape and attachments of the corner vessels are very different from those of the larger extra-alveolar vessels, and it is unlikely that the pressure outside them varies in the same way when the lung expands.

The extra-alveolar vessels are surrounded by a potential perivascular space, which has an important role in the transport of extravascular fluid in the lung. The lymph vessels run in this space, although lymph can also traverse the space outside lymph vessels. One of the earliest histologic signs of interstitial pulmonary edema is “cuffing” of the perivascular space around the extra-alveolar vessels.^{18,19} A distinction should be drawn between the net pressure (sum of forces per unit area) pulling on the wall of an extra-alveolar vessel on the one hand, and the fluid hydrostatic pressure in the perivascular space on the other. The fluid hydrostatic pressure determines the movement of fluid into this region, and there is evidence that this pressure is very low compared with the hydrostatic pressure in the interstitium of the alveolar wall. As a consequence, fluid that passes from the capillaries into the interstitial space of the alveolar wall eventually finds its way to the perivascular low-pressure region by virtue of the hydrostatic pressure gradient.²⁰

PULMONARY VASCULAR RESISTANCE

Pulmonary vascular resistance is given by the following relationship:

$$\text{Pulmonary vascular resistance} = \frac{\text{Pulmonary arterial pressure} - \text{pulmonary venous pressure}}{\text{Pulmonary blood flow}} \quad [10]$$

Because all three variables vary between systole and diastole, mean values are generally used. This definition is similar to that used for electrical resistance, which is the difference of voltage across a resistor divided by the current. However, whereas the resistance of an electrical resistor is independent of the voltage at both ends and the current, this is not the case for pulmonary vascular resistance. For example, an increase in either pulmonary arterial pressure or pulmonary venous pressure generally results in a decrease in pulmonary vascular resistance because as capillary pressure rises, there is both capillary recruitment and distention (see later). Similarly, if pulmonary blood flow is

increased (e.g., by raising pulmonary arterial pressure), pulmonary vascular resistance usually decreases.

It is important to appreciate that a single number for pulmonary vascular resistance is a very incomplete description of the pressure-flow properties of the pulmonary circulation. However, in practice, pulmonary vascular resistance is often a useful measurement because, although the normal value varies considerably, we often wish to compare the normal lung with a markedly abnormal one in which the vascular resistance is greatly increased.

In practice, pulmonary venous pressure is difficult to measure. Therefore the ratio of pulmonary artery pressure to blood flow is sometimes reported and is termed *total pulmonary vascular resistance*. An estimate of pulmonary venous pressure can be obtained by wedging a catheter in a small pulmonary artery (the so-called pulmonary wedge pressure).

Pressure-Flow Relations

If pulmonary blood flow is measured in an isolated, perfused lung, when pulmonary arterial pressure is raised (while pulmonary venous pressure, alveolar pressure, and lung volume are held constant), then flow increases relatively more than pressure (Fig. 4-8). This figure shows that pulmonary vascular resistance decreases both when pulmonary arterial pressure is raised and when pulmonary venous pressure is raised (other pressures held constant) even as flow now falls. The unifying explanation for reduced resistance in both cases is vascular distention and recruitment due to raised intravascular pressure.

The decreases in pulmonary vascular resistance shown in Figure 4-8 help to limit the work of the right heart under conditions of high pulmonary blood flow. For example, during exercise, both pulmonary arterial and venous pressures rise. Although the normal pulmonary vascular resistance is remarkably small (the normal 5 L/min pulmonary blood flow is associated with an arterial-venous pressure difference of only approximately 10 mm Hg), the resistance falls to even lower values when the pulmonary arterial and venous pressures rise, as during exercise.

Two mechanisms responsible for the fall in pulmonary vascular resistance are *recruitment*, that is, opening up of previously closed blood vessels, and *distention*, that is, increase in caliber of vessels. Figure 4-9A shows experimental data from rapidly frozen dog lung preparations, indicating the importance of recruitment as the pulmonary arterial pressure is raised from low values.²¹ Note that the number of open capillaries per millimeter of length of alveolar wall increased from approximately 25 to over 50 as pulmonary arterial pressure was raised from zero to almost 15 cm H₂O. Figure 4-9B shows data on the importance of distention of pulmonary capillaries.¹⁷ Note that the mean width of the capillaries increased from approximately 3.5 to nearly 7 μ m as the capillary pressure was increased to approximately 50 cm H₂O. Beyond that, there was very little change.

Figure 4-8 The drop in pulmonary vascular resistance (PVR) seen as the pulmonary arterial or venous pressure is raised in a canine lung preparation. When one pressure was changed, the other was held constant. (Redrawn from West JB: *Respiratory physiology—the essentials*, ed 9, Baltimore, 2012, Lippincott Williams & Wilkins.)

Figure 4-9 **A**, Recruitment of pulmonary capillaries as the pulmonary arterial pressure, the perfusing pressure, is raised. **B**, Distention of pulmonary capillaries as their pressure is increased. (**A**, Redrawn from Warrell DA, Evans JW, Clarke RO, et al: Pattern of filling in the pulmonary capillary bed. *J Appl Physiol* 32:346–356, 1972. **B**, Redrawn from Glazier JB, Hughes JMB, Maloney JE, West JB: Measurements of capillary dimensions and blood volume in rapidly frozen lungs. *J Appl Physiol* 26:65–76, 1969.)

The mechanism of recruitment of pulmonary capillaries is not fully understood. It has been suggested that, as the pulmonary arterial pressure is increased, the critical opening pressures of various arterioles are successively overcome. However, it has been shown that the red blood cell concentration, used as a measure of perfusion, varied within areas supplied by single arterioles indicating that capillaries, not arterioles, probably accounted for the heterogeneous perfusion.²¹ This suggests that vessels are recruited at the capillary rather than the arterial level.

A possible mechanism of recruitment of pulmonary capillaries is based on the stochastic properties of a dense network of numerous interconnected capillary segments.²² It can be shown in such a model that, if each capillary segment requires a very small critical pressure before flow begins and the network contains a distribution of these critical pressures, capillaries can be recruited over a large range of arterial pressures. For example, in a network with as many elements as in the human pulmonary capillary bed,¹ a critical pressure of the order of only 0.02 cm H₂O for the individual segments could result in recruitment over a range of arterial pressures from 0 to 30 cm H₂O. Such a very small critical pressure could result from the intrinsic flow properties of blood, especially when the diameter of the red cells equals that of the capillary lumen.

The mechanism of distention of pulmonary capillaries is apparently simply the bulging of the capillary wall as the transmural pressure of the capillaries is raised. As [Figure 4-9B](#) shows, the mean capillary diameter increases as capillary transmural pressure rises. Probably this behavior is caused by a change in shape of the capillaries rather than actual stretching of the capillary wall. There is evidence that the strength of the wall (at least on the thin side) comes from the type IV collagen in the basement membranes (see later), which has a high tensile strength and Young's modulus (i.e., it is very stiff). It is unlikely that it stretches appreciably when the capillary transmural pressure rises to 30 cm H₂O. However, surface tension forces and also longitudinal tension in the alveolar wall associated with lung inflation tend to flatten the capillaries at low capillary transmural pressures, and this means that their diameter can increase when capillary pressure rises. In photomicrographs of rapidly frozen lung preparations, pulmonary capillaries with very high intracapillary pressures show remarkable bulging.¹⁷

Recruitment and distention also provide mechanisms for increasing both the surface area of the lung microvasculature in contact with alveolar gas and the red cell transit time through the microvasculature, which may facilitate gas exchange.

Effect of Lung Volume

Lung volume has an important influence on pulmonary vascular resistance. [Figure 4-10](#) shows that, as lung volume is increased from very low values, vascular resistance first decreases and then increases. The lung normally operates near the minimal value of vascular resistance, that is, FRC coincides with a low vascular resistance.

The increase in pulmonary vascular resistance at very low lung volume is caused by the decrease in caliber of the extra-alveolar vessels. Because these vessels are normally held open by the radial traction of the surrounding paren-

Figure 4-10 Effect of changing lung volume on pulmonary vascular resistance. Data were taken from a canine lung preparation. (Redrawn from West JB: *Respiratory physiology—the essentials*, ed 9, Baltimore, 2012, Lippincott Williams & Wilkins.)

chyma, their caliber is least in the collapsed lung. Under these conditions the presence of elastic tissue and smooth muscle with tone in the wall of these vessels may result in a critical opening pressure of approximately 7 cm H₂O.²³ Also, at low lung volumes, vascular resistance is extremely sensitive to vasoconstrictor drugs, such as serotonin, which cause contraction of vascular smooth muscle.²⁴

Another factor that may contribute to the high pulmonary vascular resistance at low states of lung inflation is folding and distortion of pulmonary capillaries.^{25,26} However, the possible importance of distortion of the pulmonary capillaries as a cause of the increase of vascular resistance at low lung volumes is still uncertain.

At high states of lung inflation, the increase in pulmonary vascular resistance is probably caused by narrowing of the pulmonary capillaries. An analogy is a piece of thin rubber tubing that narrows considerably when it is stretched across its diameter. This distortion increases the resistance to fluid moving through it. Direct measurements on rapidly frozen dog lungs show that the mean width of the capillaries is greatly decreased at high states of lung inflation.¹⁷

In considering the effects of lung inflation, a distinction should be made between “positive” and “negative” pressure inflation. The results shown in [Figure 4-10](#) were found with negative-pressure inflation, that is, when the lung was expanded by reducing pleural pressure and the relationship between pulmonary arterial and alveolar pressures was held constant. If positive-pressure inflation is used (i.e., alveolar pressure is increased with respect to pulmonary arterial pressure), pulmonary vascular resistance increases even more at high states of lung inflation. The reason is that lung inflation is then associated with a decrease in the transmural pressure of the capillaries and they are, in effect, squashed by the increased alveolar pressure. This is actually the case in normal subjects, for example, during inhalation to total lung capacity. Although alveolar pressure remains at atmospheric pressure at the end of inspiration (glottis open), pulmonary arterial and venous pressures fall along with intrapleural pressure. Thus the net result is to decrease the transmural pressure across the pulmonary capillaries, and this is an additional contributing factor in the increase of pulmonary vascular resistance.

Other Factors Affecting Pulmonary Vascular Resistance

Various drugs affect pulmonary vascular resistance. In some instances, the effects depend on the species of animal. However, in general, serotonin, histamine, and norepinephrine cause contraction of pulmonary vascular smooth muscle and increase vascular resistance. These drugs are particularly effective as vasoconstrictors when the lung volume is small and the radial traction of surrounding parenchyma on the extra-alveolar vessels is weak. Drugs that often relax smooth muscle in the pulmonary circulation include acetylcholine and isoproterenol. However, normal pulmonary blood vessels have little resting tone, so the degree of potential relaxation is small.

The autonomic nervous system exercises a weak control on the pulmonary circulation. There is evidence that increased sympathetic tone can cause vasoconstriction and stiffening of the walls of the larger pulmonary arteries. Both α - and β -adrenergic receptors are present.²⁷ Increased parasympathetic activity has a weak vasodilator action. As already indicated, any changes of vascular smooth muscle tone are much more effective at low states of lung inflation (when the extra-alveolar vessels are narrowed) or in the fetal state (when the amount of smooth muscle present is much greater than in the adult).

Pulmonary edema increases vascular resistance by a mechanism that is poorly understood. It may be that there are different mechanisms, depending on the type and stage of edema. Interstitial pulmonary edema causes marked cuffing of the perivascular spaces of the extra-alveolar vessels. Presumably this increases their vascular resistance,²⁸ because, as already indicated, these vessels rely on the radial traction of the surrounding parenchyma to hold them expanded. In addition, however, it may be that edema in the interstitium of the alveolar wall encroaches on the pulmonary capillaries to some extent, thus increasing their vascular resistance.²⁹ Pulmonary edema results in reduced ventilation of the most affected regions. This (see [gas exchange](#) section) reduces their local alveolar P_{O_2} , and this in turn may stimulate what is known as hypoxic pulmonary vasoconstriction. This is discussed in a later section and in Chapter 6.

DISTRIBUTION OF PULMONARY BLOOD FLOW

Just as for ventilation, blood flow is not partitioned equally to all alveoli, even in the normal lung. Both gravitational (topographic) and nongravitational factors affect the distribution of blood flow.

Normal Distribution

The topographic distribution of pulmonary blood flow can conveniently be measured using radioactive materials. In one technique, ^{133}mXe is dissolved in saline and injected into a peripheral vein. When the xenon reaches the pulmonary capillaries, it evolves into the alveolar gas because of its low blood solubility. The resulting distribution of radioactivity within the lung can be measured using a gamma camera or similar device and reflects the regional distribution of blood flow. Subsequently the distribution of alveolar volume is obtained by having the subject rebreathe radioactive

xenon to equilibrium. By combining the two measurements, the blood flow per unit alveolar volume of the lung can be obtained. The distribution of blood flow can also be measured with radioactive albumin macroaggregates and with a variety of other radioactive gases, including ^{15}O -labeled carbon dioxide and ^{13}N . Functional magnetic resonance imaging of the lung has been used to assess distribution of pulmonary blood flow.³⁰ This noninvasive technique does not expose subjects to radioactivity; therefore it can be used repetitively and shows great promise for the future.

In the normal upright human lung, pulmonary blood flow decreases approximately linearly with distance up the lung, reaching very low values at the apex.³¹ However, if the subject lies supine, apical and basal blood flow become the same, and now blood flow is less in the anterior (uppermost) than posterior (lowermost) regions of the lung. Thus blood flow distribution is highly dependent on gravitational effects. During exercise in the upright position, both apical and basal blood flow rates increase and the relative differences are reduced.

The factors responsible for the uneven topographic distribution of blood flow can be studied conveniently in isolated lung preparations. These studies show that, in the presence of normal vascular pressures, blood flow decreases approximately linearly up the lung³² as it does in intact humans. However, if the pulmonary arterial pressure is reduced, blood flows only up to the level at which pulmonary arterial equals alveolar pressures; above this point, no flow can be detected. If venous pressure is raised, the distribution of blood flow may become more uniform in the region of the lung below the point at which pulmonary venous equals alveolar pressure.

Three-Zone Model for the Distribution of Blood Flow

Figure 4-11 shows a simple model for understanding the factors responsible for the topographic inequality of blood

Figure 4-11 Three-zone model designed to account for the uneven topographic distribution of blood flow in the lung. Pa, pulmonary arterial pressure; PA, pulmonary alveolar pressure; PV, pulmonary venous pressure. (Redrawn from West JB, Dollery CT, Naimark A: Distribution of blood flow in isolated lung: relation to vascular and alveolar pressures. *J Appl Physiol* 19:713–724, 1964.)

flow in the lung.³² The lung is divided into three zones according to the relative magnitudes of the pulmonary arterial, alveolar, and venous pressures.

Zone 1 is that region of the lung above the level at which pulmonary arterial equals alveolar pressures; in other words, in this region, alveolar pressure exceeds arterial pressure. Measurements in isolated lungs show that there is no blood flow in zone 1, the explanation being that the collapsible capillaries close because the pressure outside exceeds the pressure inside. Micrographs of rapidly frozen lung from zone 1 show that the capillaries have collapsed, although occasionally trapped red blood cells can be seen within them.¹⁷

The vertical level of blood flow can be influenced by the surface tension of the alveolar lining layer, as discussed earlier. If measurements are made on a lung immediately after it is inflated from a near-collapsed state, blood flow reaches 3 or 4 cm above the level at which pulmonary arterial and alveolar pressures are equal.¹⁶ This can be explained by the reduced surface tension, which lowers the pericapillary hydrostatic pressure.

Zone 2 is that part of the lung in which pulmonary arterial pressure exceeds alveolar pressure, but alveolar pressure exceeds venous pressure. Here the vessels behave like Starling resistors,³³ that is, as collapsible tubes surrounded by a pressure chamber. Under these conditions, flow is determined by the difference between arterial and alveolar pressures, rather than by the expected arterial-venous pressure difference. One way of looking at this is that the thin wall of the vessel offers no resistance to the collapsing pressure, so the pressure inside the tube at the downstream end is equal to chamber pressure. Thus the pressure difference responsible for flow is perfusion minus chamber pressure. This behavior has been variously referred to as the water-fall³³ or sluice³⁴ effect and can be demonstrated in rubber-tube models on the laboratory bench. The increase in blood flow down zone 2 can be explained by the hydrostatic increase in pulmonary arterial pressure down the zone, whereas the alveolar pressure remains constant. Thus the pressure difference determining flow increases linearly with distance.

Zone 3 is that part of the lung in which venous pressure exceeds alveolar pressure. Radioactive gas measurements show that blood flow increases as one measures vertically down this zone, although, in some preparations at least, the rate of increase is apparently less than found in zone 2. Because the pressure difference responsible for flow is arterial minus venous pressure and because these two pressures increase similarly with distance down the zone, the increase in blood flow is not explained by changes in perfusing pressure. Instead, blood flow increases down this zone because vascular resistance falls with distance down the zone, likely because of progressive distention (confirmed histologically¹⁷) from the increasing transmural pressure (intravascular pressure increasing down the zone while alveolar pressure is constant). However, resistance may also be reduced by recruitment of capillaries.

The Effect of Lung Volume on the Distribution of Blood Flow—Zone 4

In spite of its simplicity, the three-zone model of [Figure 4-11](#), based on the effects of pulmonary arterial, alveolar,

and venous pressures, accounts for many of the distributions seen in the normal lung. However, other factors play a role; one of these is lung volume. For example, under most circumstances, a zone of reduced blood flow, known as zone 4, is seen in the lowermost region of the upright human lung.³⁵ This zone becomes smaller as lung volume is increased, but careful measurements indicate that a small area of reduced blood flow is present at total lung capacity at the lung base. As lung volume is reduced, this region of reduced blood flow extends further and further up the lung, so that at FRC, blood flow decreases in the bottom half of the lung. At RV the zone of reduced blood flow extends all the way up the lung, so that blood flow at the apex exceeds that at the base.³⁵

These patterns cannot be explained by the interactions of the pulmonary arterial, venous, and alveolar pressures as in [Figure 4-11](#). Instead, we have to take into account the contribution of the extra-alveolar vessels. As pointed out previously (see [Fig. 4-10](#)), the caliber of these vessels is determined by the degree of lung inflation; as lung volume is reduced, the vessels narrow. In the upright human lung, the alveoli are less well expanded at the base than at the apex because of distortion of the elastic lung caused by its weight (see [Fig. 4-5](#)). As a result the extra-alveolar vessels are relatively narrow at the base, and their increased contribution to pulmonary vascular resistance results in the presence of a zone of reduced blood flow in that region. As overall lung volume is reduced, the contribution of the extra-alveolar vessels to the distribution of blood flow increases, and zone 4 extends further up the lung. At residual volume the caliber of the extra-alveolar vessels is so small that they completely dominate the picture and determine the distribution of blood flow.

Vasoactive drugs and interstitial edema can modify the contribution of extra-alveolar vessels to pulmonary vascular resistance. For example, the role of the extra-alveolar vessels can be exaggerated by injecting vasoconstrictor drugs such as serotonin.³⁶ Under these conditions, zone 4 extends even further up the lung. The opposite effect is seen if a vasodilator drug such as isoproterenol is infused into the pulmonary circulation. With interstitial edema, the contribution of the extra-alveolar vessels increases, because the edema creates a cuff of fluid around the vessels and thereby narrows them. This is thought to be the cause of the increased pulmonary vascular resistance seen at the base of the human lung in conditions of interstitial pulmonary edema,²⁸ in which the distribution of blood flow often becomes inverted (e.g., in chronic mitral stenosis).³⁷ Under these conditions the blood flow to the apex of the upright lung consistently exceeds the flow to the basal regions. However, the effects of interstitial edema on blood flow distribution are still not fully understood.

Other Factors Affecting the Distribution of Blood Flow

Because the topographic distribution of blood flow in the normal lung can be attributed to gravity, it is not surprising that, during increased acceleration, the distribution of blood flow becomes more uneven.³⁸ For example, during exposure to +3g acceleration, that is, three times the normal acceleration experienced by someone in the upright posture,

the upper half of the lung is completely unperfused. The amount of unperfused lung is approximately proportional to the g level.

By contrast, in astronauts during sustained microgravity in space, the distribution of blood flow becomes more uniform.³⁹ Because it is not possible to use radioactive gases in this environment, the inequality of blood flow has been determined indirectly from the size of the cardiogenic oscillations for PCO_2 . Cardiogenic oscillations are fluctuations in the concentrations of gases such as oxygen, carbon dioxide, and nitrogen during a single expiration. They have the same frequency as heart rate and are considered to be caused by differential rates of emptying of different parts of the lung due to contraction and dilatation of the heart exerting direct pressure on nearby but not distant lung parenchyma. For oscillations to be detected, these differentially emptying regions must also have different alveolar PO_2 and PCO_2 values, and this happens when blood flow and ventilation are not uniformly distributed throughout the lung. Microgravity almost abolishes cardiogenic oscillations, implying greater uniformity in the distribution of blood flow and/or ventilation in the absence of gravity. Interestingly, because these oscillations can still be seen, albeit to a much smaller extent than on earth, some inequality remains, indicating that gravity-independent mechanisms are also present.

Although gravity is a major factor determining the uneven distribution of blood flow in the upright human lung, it is now clear that nongravitational factors also play an important role. There are several possible mechanisms. One is that there may be regional differences of vascular conductance, with some regions of the pulmonary vasculature having an intrinsically higher vascular resistance than others. This has been shown to be the case in isolated dog lungs,⁴⁰ and there is some evidence for higher blood flows in the dorsal-caudal than the ventral regions of the lung in both intact dogs and horses. Another possible factor is a difference in blood flow between the central and peripheral regions of the lung,⁴¹ although this finding is controversial. Some measurements show differences in blood flow along the acinus, with the more distal regions of the acinus being less well perfused than the proximal regions.^{42,43} Finally, as pointed out earlier, because of the complexity of the pulmonary circulation at the alveolar level, including the very large number of capillary segments, it is likely that there is inequality of blood flow at this level. Reference has already been made to the possibility of recruitment of pulmonary capillaries based on the stochastic properties of a dense network of numerous interconnected capillary segments.²² There is also work suggesting that the distribution of pulmonary blood flow in small vessels may follow a fractal pattern.⁴⁴ The term *fractal* describes a branching pattern of both structure (blood vessels) and function (blood flow) that repeats itself with each generation. This means that any subsection of the vascular tree exhibits the same branching pattern as the entire tree. Were a picture of such a subsection to be enlarged, it would overlap and match the pattern of the whole tree. Just as mentioned for ventilation earlier, repeated branching of blood vessels has implications for how blood flow is distributed independently of gravitational influences. The greater the number of branch points, the greater the likely inequality of perfusion among alveoli. This implies that the finer the spatial resolution of the

method used to assess flow distribution, the greater the amount of inequality likely to be detected.

Abnormal Patterns of Blood Flow

The normal distribution of pulmonary blood flow is frequently altered by lung and heart disease. Localized lung disease, such as fibrosis and cyst formation, usually causes a local reduction of flow. The same is true of pulmonary embolism, in which the local reduction in blood flow, as determined from a perfusion scan, is usually coupled with normal ventilation, and this pattern provides important diagnostic information. Bronchial carcinoma may reduce regional blood flow, and occasionally a small hilar lesion can cause a marked reduction of blood flow to one lung, presumably through compression of the main pulmonary artery. Generalized lung diseases, such as COPD and bronchial asthma, also frequently cause patchy inequality of blood flow. Sometimes, asthmatic patients whose disease is thought to be fairly well controlled show marked impairment of blood flow in some lung regions.

Heart disease frequently alters the distribution of blood flow, as might be expected from the factors responsible for the normal distribution (see Fig. 4-11). For example, patients with pulmonary hypertension or increased blood flow through left-to-right shunts usually show a more uniform distribution of blood flow.⁴⁵ Diseases in which pulmonary arterial pressure is reduced, such as tetralogy of Fallot with oligemic lungs, are associated with reduced perfusion of the lung apices. Increased pulmonary venous pressure, as in mitral stenosis, initially causes a more uniform distribution than normal. However, in advanced disease, an inversion of the normal distribution of blood flow is frequently seen, with more perfusion to the upper than to the lower zones. The mechanism for this shift is not fully understood, but, as indicated earlier, perivascular edema causing an increased vascular resistance of the extra-alveolar vessels is thought to be a factor.

ACTIVE CONTROL OF THE PULMONARY CIRCULATION

The distribution of pulmonary blood flow and the pressure-flow relations of the pulmonary circulation are normally dominated by the passive effects of the hydrostatic pressure gradient described earlier. Thus the roles of gravity, of variation in vascular lengths and diameters, and of recruitment and distention can account for much of the behavior of the normal circulation. The normal adult pulmonary circulation has a limited amount of smooth muscle in the walls of the vessels, and active control of vascular tone is weak. However, in some conditions, there is an increase in the amount of smooth muscle. This is the case in the fetal lung, in long-term residence at high altitude, and in prolonged pulmonary hypertension. In these situations the tone of the vascular smooth muscle plays a more significant role. However, some active control of the circulation is seen in the normal lung.

Hypoxic Pulmonary Vasoconstriction

In a region of a lung with alveolar hypoxia, vascular smooth muscle contracts and raises local vascular resistance, which may reduce blood flow. The precise mechanism of such

hypoxic pulmonary vasoconstriction is still not known, but, because it can be observed in excised isolated lungs, it clearly does not depend on central nervous system connections. Furthermore, excised segments of pulmonary artery can be shown to constrict if their environment is made hypoxic, so it appears to be a local action of the hypoxia on the artery itself. It is also known that it is the PO_2 of the alveolar gas, not of the pulmonary arterial blood, that chiefly determines the response.⁴⁶ This can be proved by perfusing a lung with blood with a high PO_2 while keeping the alveolar PO_2 low; under these conditions the vasoconstrictive response is still seen.

The mechanisms of hypoxic pulmonary vasoconstriction are still not fully understood. Studies indicate that voltage-gated potassium channels in the smooth muscle cells are involved, leading to increased intracellular calcium ion concentrations.⁴⁷⁻⁵⁰ There may be roles for vasoactive substances generated by the endothelial cell. More details are covered in Chapter 6.

Endothelium-derived vasoactive substances play a role. Nitric oxide (NO) is an endothelium-derived relaxing factor for blood vessels. It is formed from L-arginine and is a final common pathway for a variety of biologic processes. NO activates soluble guanylate cyclase, which leads to smooth muscle relaxation by the synthesis of cyclic guanosine monophosphate. Inhibitors of NO synthesis augment hypoxic pulmonary vasoconstriction in animal preparations, and inhaled NO reduces hypoxic pulmonary vasoconstriction in humans.⁵¹ The required inhaled concentration of NO is extremely low (approximately 20 parts per million), and the gas is very toxic at high concentrations. The effects of NO on ventilation-perfusion matching (see later) and arterial PO_2 in patients with lung disease depends on whether vasodilatation increases perfusion of well-ventilated regions of the lung or not.⁵²

Vasoconstrictor peptides, known as endothelins and released by pulmonary vascular endothelial cells, may participate as well.⁵³ Their role in normal physiologic processes and disease is still being evaluated, but endothelin antagonists have become important therapeutic agents in pulmonary arterial hypertension.

The stimulus-response curve of hypoxic pulmonary vasoconstriction is very nonlinear (Fig. 4-12). When the alveolar PO_2 is altered in the region above 100 mm Hg, little change in vascular resistance is seen. However, when the alveolar PO_2 is reduced to approximately 70 mm Hg, vasoconstriction begins, and, at a very low PO_2 approaching that of mixed venous blood, the local blood flow may be almost abolished. The data shown in Figure 4-12 are from anesthetized cats.⁵⁴ However, there are species differences in the stimulus-response curves. For example, in the coatimundi (a small South American mammal), there is an almost linear reduction of blood flow between alveolar PO_2 values of 150 and 40 mm Hg.⁵⁵ The preparation in which these measurements were made had the additional advantages that the chest was closed and the measurements were made in a very small region of lung. These conditions probably give the best information on the role of the phenomenon in the local regulation of blood flow.

The major site of the vasoconstriction is in the small pulmonary arteries.⁵⁶ In the normal human lung the small arteries have a meager amount of smooth muscle, which

Figure 4-12 Stimulus-response curves of hypoxic pulmonary vasoconstriction. Pulmonary blood flow is shown in relation to alveolar PO_2 in feline lung preparations. (Redrawn from Barer GR, Howard P, Shaw JW: Stimulus-response curves for the pulmonary vascular bed to hypoxia and hypercapnia. *J Physiol [Lond]* 211:139-155, 1970.)

may be uneven in its distribution. This may explain why, even in global alveolar hypoxia (e.g., at high altitude), vasoconstriction is nonetheless uneven. For example, alveolar hypoxia nearly doubles the dispersion of transit times through the pulmonary circulation of a lobe of dog lung,⁵⁷ and the distribution of India ink particles injected into the pulmonary circulation during alveolar hypoxia is more uneven than during normoxia.⁵⁸ This uneven vasoconstriction probably plays a role in the mechanism of high-altitude pulmonary edema⁵⁹ (see later).

Hypoxic pulmonary vasoconstriction has the effect of directing blood flow away from hypoxic regions of lung, which is beneficial to gas exchange. Other things being equal, this reduces the amount of ventilation-perfusion inequality in a diseased lung and limits the depression of the arterial PO_2 . An example of this is seen in patients with asthma when they are treated with certain bronchodilators. These sometimes reduce arterial PO_2 as a result of an increase in blood flow to poorly ventilated areas.^{60,61} In patients with severe COPD with elevated pulmonary arterial pressure, prolonged nocturnal treatment with oxygen has been shown to reduce the degree of pulmonary hypertension and to improve the prognosis in these patients. The mechanism is presumably gradual inhibition by hyperoxia of increased smooth muscle tone originally caused by the hypoxia. The reduction in pulmonary hypertension in turn reduces afterload on the right ventricle.

Residence at high altitude results in hypoxic pulmonary vasoconstriction, both in newcomers and in permanent residents. The increase in pulmonary arterial pressure is especially marked during exercise. If 100% oxygen is given to normal subjects after they have been exposed to hypoxia for as little as 2 weeks, the pulmonary arterial pressure does not immediately return to the normal level.⁶² This suggests that hypoxia has already induced some structural change in the pulmonary vessels and new experiments show changes in ion channels controlling smooth muscle contraction in pulmonary vessels that depend on HIF-1 α .^{62a} There is considerable variation in the response of pulmonary arterial pressure to alveolar hypoxia, leading some investigators to divide people into “responders” and “nonresponders.”

Probably the most important role for hypoxic pulmonary vasoconstriction is in the perinatal period. During fetal life, when the lungs do not undertake gas exchange, pulmonary vascular resistance is very high, partly because of hypoxic vasoconstriction, and only some 15% of the cardiac output flows through the lungs. The rest bypasses the lungs via the ductus arteriosus. The vasoconstriction is particularly effective because of the abundance of smooth muscle in the pulmonary arteries. At birth, when the first few breaths oxygenate the alveoli, the vascular resistance falls dramatically because of relaxation of vascular smooth muscle, and pulmonary blood flow increases enormously. In this situation the release of hypoxic vasoconstriction is critical in the transition from placental to air breathing, and it is this situation that is presumably responsible for the evolutionary pressure to maintain the phenomenon.

Other Physiologic Substances Affecting the Pulmonary Circulation

Many peptides and other substances can potentially alter the tone of muscular pulmonary blood vessels, although the roles of these substances under physiologic conditions are still being clarified.⁶³ They include angiotensin II, bradykinin, vasopressin, atrial natriuretic peptide, endothelin, somatostatin, products of both the cyclooxygenase and lipoxygenase arms of the arachidonic acid cascade, and calcitonin gene-related peptide. Some substances show species differences, and some evoke either vasoconstriction or vasodilation, depending on their concentration. Biogenic amines such as acetylcholine, histamine, serotonin, and norepinephrine also affect pulmonary vascular smooth muscle.

DAMAGE TO PULMONARY CAPILLARIES BY HIGH WALL STRESSES

The blood-gas barrier has a basic dilemma. On the one hand, the barrier has to be extremely thin to allow efficient gas exchange by passive diffusion. On the other hand, the blood-gas barrier must be immensely strong because of the large mechanical stresses that develop in the capillary wall when the pressure in the capillaries rises or when the wall is stretched by inflating the lung to high volumes. There is evidence that the blood-gas barrier is just strong enough to withstand the highest stresses to which it is normally subjected. Unusually high capillary pressures or lung volumes result in ultrastructural damage or "stress failure" of the capillary wall, leading to a high-permeability type of pulmonary edema, or even pulmonary hemorrhage.

When the capillary transmural pressure is raised in animal preparations, disruption of the capillary endothelium, alveolar epithelium, or sometimes all layers of the capillary wall is seen. In the rabbit lung the first changes are seen at a transmural pressure of approximately 24 mm Hg, and the frequency of breaks increases as the pressure is raised.⁶⁴ Although at first sight these capillary pressures seem to be very high, there is now good evidence that the capillary pressure rises to the mid-30s (mm Hg) in the normal lung during heavy exercise.⁶⁵ This is largely secondary to the increase in left ventricular filling pressure.⁶⁶

It can be shown that, at these increased capillary transmural pressures, the "hoop" or circumferential stresses in

the capillary wall become extremely high. Indeed, they approach the breaking stress of collagen. The main reason for the very high stresses is the extreme thinness of the wall, which, in the human lung, is less than 0.3 μm in some places. It is now believed that the strength of the blood-gas barrier on the thin side comes from type IV collagen in the basement membranes. The thickness of the type IV collagen layer is only approximately 50 nm.

Stress failure is the mechanism of several clinical conditions characterized by high-permeability pulmonary edema or hemorrhage.⁶⁷ Neurogenic pulmonary edema has been shown to be associated with very high capillary pressures, the edema is of the high-permeability type, and ultrastructural damage to the capillaries has been demonstrated, consistent with stress failure. High-altitude pulmonary edema is apparently caused by uneven hypoxic pulmonary vasoconstriction (referred to earlier), which allows some of the capillaries to be exposed to high pressure.⁶⁸ Again, the edema is of the high-permeability type, and typical ultrastructural changes in the capillaries have been demonstrated in animal preparations.⁶⁹

A particularly interesting condition is seen in racehorses, which can suffer bleeding into the lungs while galloping. This is very common and is caused by the extremely high pulmonary capillary pressures, which approach 100 mm Hg. Direct evidence of stress failure of pulmonary capillaries has been shown in these animals.⁷⁰ In fact, there is evidence that elite human athletes develop some ultrastructural changes in their blood-gas barrier during extreme exercise because significantly higher concentrations of red blood cells, total protein, and leukotriene B₄ are seen in their bronchoalveolar lavage fluid than in sedentary controls.⁷¹ This only happens at extremely high levels of exercise.⁷² A similar group of athletes who exercised at submaximal levels for 1 hour showed no changes in the bronchoalveolar lavage fluid.⁷³

Overinflation of the lung is known to increase the permeability of pulmonary capillaries. Stress failure is apparently the mechanism because it has been shown that, for the same capillary transmural pressure, the frequency of capillary wall damage is greatly increased at high lung volumes.⁷⁴ This is because some of the increased tension in the alveolar wall associated with lung inflation is transmitted to the capillary wall. This may be important in ventilator-induced lung injury. Finally, conditions in which the basement membrane of the capillary wall is damaged are associated with alveolar bleeding.

NONRESPIRATORY FUNCTIONS OF THE PULMONARY CIRCULATION

Although the primary purpose of the pulmonary circulation is to provide the lung with mixed venous blood so that oxygen can be added and carbon dioxide removed, the pulmonary circulation has other functions, particularly those of metabolism.

A number of vasoactive substances are metabolized by the lung.⁷⁵ Because it is the only organ whose microcirculation receives the whole cardiac output, the lung is uniquely situated to modify blood-borne substances. Indeed, a substantial fraction of all the vascular endothelial cells in the body is located in the lung.

The only known example of biologic activation by passage through the pulmonary circulation is the conversion of the relatively inactive polypeptide angiotensin I to the potent vasoconstrictor angiotensin II.⁷⁶ The latter is up to 50 times more active than its precursor but is unaffected by passage through the lung. The conversion of angiotensin I is catalyzed by an enzyme, angiotensin I-converting enzyme, which is located in small pits (caveolae intracellulares) in the surface of the capillary endothelial cells.

A number of vasoactive substances are completely or partially inactivated during passage through the lung. Bradykinin is largely inactivated (up to 80%), and the enzyme responsible is angiotensin I-converting enzyme. The lung is the major site of inactivation of serotonin (5-hydroxytryptamine), not by enzymatic degradation, but by an uptake and storage process. Some of the serotonin may be transferred to platelets in the lung or stored in some other way and released during anaphylaxis. The prostaglandins E_1 , E_2 , and $F_{2\alpha}$ are also inactivated in the lung. Norepinephrine is also taken up by the lung to some extent (up to 30%). Histamine appears not to be affected by the intact lung.⁷⁵

Some vasoactive materials pass through the lung without significant gain or loss of activity. These include epinephrine, prostaglandins A_1 and A_2 , angiotensin II, and vasopressin (also called antidiuretic hormone).

Several vasoactive substances are normally synthesized or stored within the lung but may be released into the circulation in pathologic conditions. For example, in anaphylaxis, or during an asthma attack, histamine, bradykinin, prostaglandins, and “slow-reacting substance” are discharged into the circulation. Other conditions in which the lung may release potent chemicals include pulmonary embolism (see Chapter 57) and alveolar hypoxia.

There is also evidence that the lung plays a role in the clotting mechanism of blood under normal and abnormal conditions. For example, in the interstitium, there are large numbers of mast cells containing heparin. In addition, the lung is able to secrete special immunoglobulins, particularly immunoglobulin A, in bronchial mucus, which contribute to its defenses against infection. The synthesis of phospholipids such as dipalmitoylphosphatidylcholine, a component of pulmonary surfactant (see Chapter 8), is an important function of alveolar type II cells that prevents lung collapse. Surfactant turnover is rapid, and, if the blood flow to a region of lung is obstructed (e.g., by an embolus), surfactant may become locally depleted with consequent atelectasis. Protein synthesis is also significant because collagen and elastin form the structural framework of the lung. Under abnormal conditions, proteases are apparently liberated from leukocytes or macrophages in the lung, causing breakdown of proteins and possibly emphysema (see Chapter 43). Another important activity is carbohydrate metabolism, especially the elaboration of the mucins and proteoglycans of bronchial mucus (see Chapter 10).

In addition to its metabolic functions, the lung has other functions apart from its primary gas-exchanging role. One is to act as a reservoir for blood. As stated previously, the lung has a remarkable ability to reduce its pulmonary vascular resistance through the mechanisms of recruitment and distention as vascular pressures are raised. The same mechanisms allow the lung to increase its blood volume

with relatively small rises in pulmonary arterial or venous pressures. Such changes can be seen, for example, when a subject lies down after standing and blood drains from the legs into the lung.

Another function of the lung is to filter blood. Small intravascular thrombi are removed from the circulation before they can reach the brain or other vital organs. There is also evidence that many white blood cells are sequestered by the lung, although the significance of this is not clear.

BLOOD-GAS TRANSPORT

The partial pressure of a gas is an important concept in any discussion of gas exchange, as described later the section on gas exchange. The partial pressure of a gas (P) is found by multiplying its concentration by the total pressure. For example, the PO_2 in dry room air at sea level is 159 mm Hg (0.209×760 mm Hg), where oxygen is 20.9% of room air and barometric pressure is 760 mm Hg. However, the relationship between oxygen concentration and PO_2 in blood is not linear and is commonly described by a oxygen dissociation curve. Similar considerations apply to carbon dioxide in blood. The physiologic factors that determine the oxygen and carbon dioxide dissociation curves are considered later.

OXYGEN

Oxygen is carried in the blood in two forms. A small amount is dissolved, but by far the most important component is in combination with hemoglobin.

Dissolved oxygen plays a small role in oxygen transport because the solubility of oxygen is so low (0.003 mL O_2 /100 mL blood/mm Hg). Thus normal arterial blood with a PO_2 of approximately 100 mm Hg contains only 0.3 mL of dissolved oxygen per 100 mL, whereas approximately 20 mL is combined with hemoglobin.

Dissolved oxygen can become important under some conditions. The most common is when a patient is given 100% oxygen to breathe. This typically raises the alveolar PO_2 to over 600 mm Hg, with the result that, if the lungs are normal, the dissolved oxygen may increase from 0.3 to approximately 2 mL/100 mL blood. This dissolved oxygen then becomes a significant proportion of the normal arterial-venous oxygen concentration difference of approximately 5 mL O_2 /100 mL blood.

Hemoglobin consists of heme, an iron-porphyrin compound, and a protein (globin) that has four polypeptide chains. There are two types of chains, α and β , and differences in their amino acid sequences give rise to different types of human hemoglobin. The newborn infant has predominantly hemoglobin F (fetal), which is gradually replaced over the first year or so of postnatal life. The abnormal hemoglobin, hemoglobin S (sickle), has a reduced affinity for oxygen, and, in addition, the deoxygenated form tends to crystallize within the red cell. This causes the cell shape to change from biconcave to sickle, and the result is an increased fragility and likelihood of thrombus formation. Many abnormal hemoglobins with altered oxygen affinities have been described.

Methemoglobin is formed when the ferrous ion of normal hemoglobin A is oxidized to the ferric form, often as a result of exposure to various drugs and chemicals, including nitrites, sulfonamides, and acetanilide. In one form of hereditary methemoglobinemia, there is a deficiency of the enzyme cytochrome *b5* reductase within the red cell. Methemoglobin is not useful for carrying oxygen; in addition, it increases the oxygen affinity of the remaining hemoglobin, thus impairing the unloading of oxygen to the tissues.

Cyanosis refers to the blue color of skin and mucous membranes when the hemoglobin is desaturated. It is not a reliable sign of hypoxemia; if hypoxemia is suspected, the arterial PO_2 should be measured. Cyanosis depends on the amount of reduced hemoglobin present and therefore is often marked in patients with polycythemia but is difficult to detect in the presence of anemia.

Blood is able to transport large amounts of oxygen because that molecule forms an easily reversible combination with hemoglobin (Hb) to give oxyhemoglobin (HbO_2):

The relationship between the partial pressure of oxygen and the number of binding sites of the hemoglobin that have oxygen attached is known as the *oxygen dissociation curve* (Fig. 4-13). Each gram of pure hemoglobin can combine with 1.39 mL of oxygen and, in normal blood with 15 g Hb/100 mL, the *oxygen capacity* (reached when all the binding sites are full) is 1.39×15 , or approximately 20.8 mL O_2 /100 mL of blood. The total *oxygen concentration* of a sample of blood (expressed as mL O_2 /100 mL of blood), which includes the oxygen combined with hemoglobin and the dissolved oxygen, is given by

$$\text{O}_2 \text{ concentration} = (1.39 \times \text{Hb}) \times \frac{\% \text{ saturation}}{100} + (0.003 \times \text{PO}_2) \quad [12]$$

where Hb is the hemoglobin concentration.

Figure 4-13 Oxygen dissociation curve showing typical values for arterial and mixed venous blood. The curve is shifted to the right by increases of temperature, PCO_2 , 2,3-diphosphoglycerate (DPG), and H^+ concentration. Sat, saturation. (Redrawn from West JB: *Respiratory physiology—the essentials*, ed 9, Baltimore, 2012, Lippincott Williams & Wilkins.)

The characteristic shape of the oxygen dissociation curve has several advantages. The fact that the upper portion is almost flat means that a fall of 20 to 30 mm Hg in arterial PO_2 in a healthy subject with an initially normal value (e.g., approximately 100 mm Hg) causes only a minor reduction in arterial oxygen concentration. However, this also means that noninvasive monitoring of oxygen saturation by pulse oximetry will often fail to indicate substantial falls in arterial PO_2 . Another consequence of the flat upper part of the curve is that the diffusive loading of oxygen in the pulmonary capillary is hastened. This results from the large partial pressure difference between alveolar gas and capillary blood that continues to exist even when most of the oxygen has been loaded. The steep lower part of the oxygen dissociation curve means that considerable amounts of oxygen can be unloaded to the peripheral tissues with only a relatively small drop in capillary PO_2 . This maintains a large partial pressure difference between the blood and the tissues, which assists in the diffusion process. A useful measure of the position of the dissociation curve is the PO_2 for 50% oxygen saturation; this is known as the P_{50} . The normal value for human blood is approximately 27 mm Hg.

Various factors affect the position of the oxygen dissociation curve (see Fig. 4-13). It is shifted to the right by an increase of temperature, hydrogen ion concentration, PCO_2 , and concentration of 2,3-diphosphoglycerate (2,3-DPG) in the red cell. A rightward shift indicates that the affinity of oxygen for hemoglobin is reduced. Most of the effect of the increased PCO_2 in reducing the oxygen affinity is due to the increased H^+ concentration. This is called the *Bohr effect*, and one consequence is that, as peripheral blood loads carbon dioxide, the unloading of oxygen is assisted. A rightward shift is also caused by 2,3-DPG, an end product of red cell metabolism.^{77,78} The concentration of 2,3-DPG can be increased in the setting of chronic hypoxia. The concentration of 2,3-DPG falls in stored blood, which can lead to blood with a high affinity for oxygen but with difficulty releasing oxygen to the tissues.

Small amounts of carbon monoxide in the blood increase the affinity of the remaining oxygen for hemoglobin and therefore cause a leftward shift of the dissociation curve. As a result, the unloading of oxygen in the peripheral tissue is hampered. In addition, of course, the oxygen concentration of the blood is reduced because some of the hemoglobin is bound to carbon monoxide. This is particularly dangerous because arterial chemoreceptors respond to decreases in PO_2 and not content, so the usual physiologic responses to hypoxemia may be absent.

CARBON DIOXIDE

Carbon dioxide is transported in the blood in three forms: dissolved (approximately 5% of the total), as bicarbonate (approximately 90%), and in combination with proteins as carbamino compounds (approximately 5%). Because carbon dioxide is some 24 times more soluble than oxygen in blood, dissolved carbon dioxide plays a much more significant role in its carriage compared to oxygen. For example, approximately 10% of the carbon dioxide that evolves into the alveolar gas from the mixed venous blood comes from the dissolved form.

Bicarbonate is formed in blood by the following hydration reaction:

The hydration of carbon dioxide to carbonic acid (and vice versa) is catalyzed by the enzyme carbonic anhydrase (CA), which is present in high concentrations in the red cells but is absent from the plasma (some carbonic anhydrase is apparently located on the surface of the endothelial cells of the pulmonary capillaries). Because the majority of the carbonic anhydrase is in the red cell, carbon dioxide is mostly hydrated there, and bicarbonate ion moves out of the red cell to be replaced by chloride ions to maintain electrical neutrality (chloride shift). Some of the hydrogen ions formed in the red cell are bound to hemoglobin, and, because reduced hemoglobin is a better proton acceptor than the oxygenated form, deoxygenated blood can carry more carbon dioxide for a given PCO_2 than oxygenated blood can (Fig. 4-14). This is known as the *Haldane effect*.

Carbamino compounds are formed when carbon dioxide combines with the terminal amine groups of blood proteins. The most important protein is the globin of hemoglobin. Reduced hemoglobin can bind more carbon dioxide than oxygenated hemoglobin, so the unloading of oxygen in peripheral capillaries facilitates the loading of carbon dioxide, whereas oxygenation has the opposite effect.

The carbon dioxide dissociation curve describing the relationship between PCO_2 and total carbon dioxide concentration is shown in Figure 4-14. Note that the curve is much more linear in its working range than the oxygen dissociation curve (see Fig. 4-13) and also that, as we have seen, the lower the saturation of hemoglobin with oxygen, the larger the carbon dioxide concentration for a given PCO_2 .

The transport of carbon dioxide by the blood plays an important role in the acid-base status of the body. This topic is discussed at length in Chapter 7.

GAS EXCHANGE

The primary function of the lungs is gas exchange, that is, to allow oxygen to move from the air into the blood and to allow carbon dioxide to move out. It is now established that movement of gas across the blood-gas interface is by simple passive diffusion—that is, by random (brownian) motion at a rate determined by temperature. Diffusion results in net transfer of molecules from an area of high to an area of low partial pressure, and active transport is not required. The structure of the lung is well suited to this mechanism of gas exchange. The blood-gas barrier is extremely thin (only $0.3 \mu\text{m}$ over much of its extent), and its area is between 50 and 100 m^2 . Because Fick’s law of diffusion states that the amount of gas that moves across a tissue sheet is proportional to its area and inversely proportional to its thickness, the blood-gas barrier is ideal for its gas-exchanging function.

An important concept in any discussion of gas exchange is partial pressure. As described earlier in “Blood-Gas Transport,” the partial pressure of a gas is the product of its concentration and the total pressure. For example, $\text{PO}_2 = 0.209 \times 760 \text{ mm Hg} = 159 \text{ mm Hg}$ in dry air with 20.9% oxygen at sea level, where the barometric pressure is 760 mm Hg. When air is inhaled into the upper airway, it is warmed and saturated with water vapor. The water vapor pressure at 37°C is 47 mm Hg. Under these conditions the total dry gas pressure is only $760 - 47 = 713 \text{ mm Hg}$. The PO_2 of moist inspired air is therefore $(20.9/100) \times 713 = 149 \text{ mm Hg}$. In general, the relationship between the partial pressure (P) and fractional concentration (F) of a gas when water vapor is present is given by $P_x = F_x (P_b - P_{\text{H}_2\text{O}})$, where P_b stands for barometric pressure and x refers to the species of gas.

Figure 4-15 shows an overview of the oxygen cascade from the air that we breathe to the tissues where it is utilized. The solid line marked “perfect” represents an ideal situation that does not actually exist but does make a useful backdrop for purposes of discussion. One of the first surprises is that, by the time the oxygen has reached the alveoli, its partial pressure has fallen from approximately 150 mm Hg to 100 mm Hg. The reason for this decline is

Figure 4-15 Scheme of the oxygen partial pressures from air to tissues. This shows a hypothetically perfect situation. (Redrawn from West JB: *Ventilation/blood flow and gas exchange*, ed 5, Oxford, 1990, Blackwell Scientific.)

that the PO_2 in the alveolar gas is determined by a balance between two factors. On the one hand, we have the essentially continuous addition of oxygen by the process of alveolar ventilation, and on the other, the continuous removal of oxygen by the pulmonary blood flow. The net result is that the alveolar PO_2 settles out at approximately 100 mm Hg.

It is true that the process of ventilation is intermittent with each breath and not continuous. By the same token, pulmonary capillary blood flow is known to be pulsatile. However, the volume of gas in the lung at FRC is sufficient to dampen these oscillations, with the result that the alveolar PO_2 varies by only 3 or 4 mm Hg with each breath, and less with each heartbeat. Thus alveolar ventilation and capillary blood flow can be regarded as continuous processes from the point of view of gas exchange. This greatly simplifies consideration of gas exchange.

In an ideal lung (see Fig. 4-15), the effluent pulmonary venous blood (which becomes the systemic arterial blood) would have the same PO_2 as that of the alveolar gas, namely, approximately 100 mm Hg. This is very nearly the case in the normal lung. However, when the arterial blood reaches the peripheral tissues, PO_2 falls substantially en route to the mitochondria. The movement of oxygen in the peripheral tissues is also essentially by passive diffusion, and the mitochondrial PO_2 is certainly considerably lower than that in arterial or mixed venous blood. Indeed, the PO_2 in the mitochondria may vary considerably throughout the body, depending on the type of tissue and its oxygen uptake. Nevertheless, it is useful to bear in mind that the mitochondria are the targets for the oxygen transport system and that any fall in the arterial PO_2 caused, for example, by inefficient pulmonary gas exchange must be reflected in a reduced tissue PO_2 , other factors being equal.

For carbon dioxide, the process is reversed. There is essentially no carbon dioxide in the inspired air, and the alveolar PCO_2 is approximately 40 mm Hg. Under normal conditions, arterial and alveolar PCO_2 values are the same, whereas the PCO_2 of mixed venous blood is in the range of 45 to 47 mm Hg. The PCO_2 of the tissues is probably quite variable, depending, for example, on the state of metabolism. Nevertheless, any inefficiency of the lung for carbon dioxide removal tends to raise the PCO_2 of the tissues, other factors being equal.

CAUSES OF HYPOXEMIA

Hypoxemia refers to a reduction in arterial PO_2 to below normal values. There are four major processes that can impair pulmonary gas exchange and cause hypoxemia when breathing room air at sea level: hypoventilation, diffusion limitation, shunt, and ventilation-perfusion inequality. These are now discussed in turn.

Hypoventilation

Hypoventilation is used here to refer to conditions in which alveolar ventilation is abnormally low in relation to oxygen uptake or carbon dioxide output. Alveolar ventilation is the volume of fresh inspired gas going to the alveoli (i.e., non-dead space ventilation), as mentioned earlier. As we shall see, hypoventilation always causes a raised arterial PCO_2 and also arterial hypoxemia (unless the patient is breathing an enriched oxygen mixture). It should be noted that other

conditions (e.g., ventilation-perfusion inequality) can also result in carbon dioxide retention, and some use the terms *hypoventilation* and *carbon dioxide retention* interchangeably. However, this can be confusing because carbon dioxide can be retained even when a patient is breathing more than normal, so we do not use the terms interchangeably.

We saw in the last section that the PO_2 of alveolar gas is determined by a balance between the rate of addition of oxygen by alveolar ventilation and the rate of removal by the pulmonary blood flow to satisfy the oxygen demands of the tissues. Hypoventilation results when the alveolar ventilation is reduced and the alveolar PO_2 therefore settles out at a lower level than normal. For the same reason the alveolar PCO_2 , and therefore arterial PCO_2 , are also raised.

Causes of hypoventilation include depression of the respiratory center by drugs, such as morphine derivatives and barbiturates; diseases of the brain stem, such as encephalitis; abnormalities of the spinal cord conducting pathways, such as high cervical dislocation; anterior horn cell diseases, including poliomyelitis, affecting the phrenic nerves or supplying the intercostal muscles; diseases of nerves to respiratory muscles (e.g., Guillain-Barré syndrome); diseases of the myoneural junction, such as myasthenia gravis; diseases of the respiratory muscles themselves, such as progressive muscular dystrophy; thoracic cage abnormalities (e.g., crushed chest); upper airway obstruction (e.g., thymoma); hypoventilation associated with extreme obesity (pickwickian syndrome); and other miscellaneous causes, such as metabolic alkalosis and idiopathic states. For discussion of hypoventilation, see Chapters 86 and 99.

Note that, in all these conditions, the lungs are normal. Thus this group can be clearly distinguished from those diseases in which the carbon dioxide retention is associated with chronic lung disease. In the latter conditions the lungs are abnormal, and a major factor in the raised PCO_2 is the ventilation-perfusion inequality that causes gross inefficiency of pulmonary gas exchange (see later).

The rise in alveolar PCO_2 as a result of hypoventilation can be calculated using the *alveolar ventilation equation* (see earlier section “[Total and Alveolar Ventilation](#)” for derivation):

$$\dot{V}_A = \frac{\dot{V}_{CO_2}}{PACO_2} \times K \quad [6]$$

where K is a constant. This can be rearranged as follows:

$$PACO_2 = \frac{\dot{V}_{CO_2}}{\dot{V}_A} \times K \quad [14]$$

Because in normal lungs the alveolar ($PACO_2$) and arterial ($PaCO_2$) PCO_2 are almost identical, we can write:

$$PaCO_2 = \frac{\dot{V}_{CO_2}}{\dot{V}_A} \times K \quad [15]$$

This very important equation indicates that the level of PCO_2 in alveolar gas or arterial blood is inversely related to the alveolar ventilation. For example, if the alveolar ventilation is halved, the PCO_2 doubles. Note, however, that this is true only after a steady state has been reestablished and the carbon dioxide production rate is the same as before. In practice, if the alveolar ventilation of a patient is suddenly decreased (e.g., by changing the setting on a ventilator), the

PCO₂ rises over a period of 10 to 20 minutes. The rise is rapid at first and then is more gradual as the body stores of carbon dioxide are gradually filled.⁷⁹

The same principles used for carbon dioxide can be applied to oxygen to understand the effect of hypoventilation on alveolar (and thus arterial) PO₂. The corresponding mass conservation equation for oxygen is as follows:

$$\dot{V}O_2 = \dot{V}I \times F_{IO_2} - \dot{V}A \times F_{AO_2} \quad [16]$$

Here, $\dot{V}I$ is inspired alveolar ventilation (sometimes written as $\dot{V}IA$), whereas $\dot{V}A$ is expired alveolar ventilation. Equation 16 expresses oxygen uptake as the difference between the amount of oxygen inhaled per minute (volume of inspired gas [$\dot{V}I$] \times fractional concentration of oxygen [F_{IO_2}]) and that exhaled per minute (volume of alveolar ventilation [$\dot{V}A$] \times fractional concentration of oxygen in alveolar gas [F_{AO_2}]). Normally, because a little more oxygen is taken up per minute than carbon dioxide exhaled, $\dot{V}I$ exceeds $\dot{V}A$. However, this difference is usually no more than 1% of the ventilation, and clinically it can most often be ignored. If this is done, $\dot{V}I$ may then be replaced by $\dot{V}A$, and Equation 16 simplifies to

$$\begin{aligned} \dot{V}O_2 &= \dot{V}A \times (F_{IO_2} - F_{AO_2}) \text{ or} \\ \dot{V}O_2 &= \dot{V}A \times \frac{(P_{IO_2} - P_{AO_2})}{K} \end{aligned} \quad [17]$$

where P_{IO_2} is the partial pressure of oxygen in the inspired gas. Thus, as ventilation falls, P_{AO_2} must fall as well to maintain the rate of oxygen uptake necessary for metabolic function. Equations 14 (reexpressed as $\dot{V}CO_2 = \dot{V}A \times P_{ACO_2}/K$) and 17 can be usefully combined. If Equation 14 is divided by Equation 17, we get

$$\frac{\dot{V}CO_2}{\dot{V}O_2} = R = \frac{P_{ACO_2}}{(P_{IO_2} - P_{AO_2})} \quad [18]$$

Here, R is the respiratory exchange ratio (volume of carbon dioxide exhaled/oxygen taken up in the same time). Both K and $\dot{V}A$ cancel out when the division is performed. Rearranging this equation yields

$$P_{AO_2} = P_{IO_2} - \frac{P_{ACO_2}}{R} \quad [19]$$

This is called the *alveolar gas equation*, and it uniquely relates alveolar PO₂ to PCO₂ for given values of inspired PO₂ and R . It is the basis of calculations of the alveolar-to-arterial PO₂ difference, a commonly used index of inefficiency of pulmonary gas exchange. Because we assumed that $\dot{V}I = \dot{V}A$ in deriving this equation, it is an approximation. It is possible to account for the difference between $\dot{V}I$ and $\dot{V}A$, and, when this is done, the alveolar gas equation contains an additional term:

$$P_{AO_2} = P_{IO_2} - \frac{P_{ACO_2}}{R} + \left[P_{ACO_2} \times F_{IO_2} \times \frac{(1-R)}{R} \right] \quad [20]$$

The term in brackets is the correction factor for the difference between inspired and expired volumes. It is generally small during air breathing (1 to 3 mm Hg) and can be ignored in most clinical settings if the patient is breathing air. However, if the patient is being given an enriched oxygen mixture, the correction factor increases; for example to 10 mm Hg in someone with normal arterial blood gas levels breathing pure oxygen.

As an example of the use of this equation, suppose that a patient with normal lungs takes an overdose of a barbiturate drug that depresses alveolar ventilation. The patient's alveolar PCO₂ might rise from 40 to 60 mm Hg (the actual value is determined by the alveolar ventilation equation). Before the drug, the patient's alveolar PO₂ can be calculated assuming $R = 1.0$, and the small correction factor is neglected:

$$\begin{aligned} P_{AO_2} &= P_{IO_2} - (P_{ACO_2}/R) \\ &= 149 - (40/1) \\ &= 109 \text{ mm Hg} \end{aligned}$$

After the drug and making the same assumptions, alveolar PO₂ falls by 20 mm Hg:

$$\begin{aligned} P_{AO_2} &= P_{IO_2} - (P_{ACO_2}/R) \\ &= 149 - (60/1) \\ &= 89 \text{ mm Hg} \end{aligned}$$

Hence, when $R = 1.0$, alveolar PO₂ falls by 20 mm Hg, which is the same amount by which the PCO₂ rises. If $R = 0.8$, which is a more typical resting value, and we ignore the small correction factor in Equation 20, then, when alveolar PCO₂ increases by 20 mm Hg, alveolar PO₂ decreases by 25 mm Hg, from 99 to 74 mm Hg.

Both examples emphasize that, in practical terms, the hypoxemia is generally of minor importance compared with the carbon dioxide retention and consequent respiratory acidosis. This is further illustrated in Figure 4-16, which shows calculated changes in gas exchange as a result of hypoventilation. Note that severe hypoventilation sufficient to double the PCO₂ from 40 to 80 mm Hg decreases the alveolar PO₂ from only, say, 100 to 50 or 60 mm Hg. Although the arterial PO₂ is likely to be a few millimeters of mercury lower than the alveolar value, the arterial oxygen saturation is approximately 80%. However, there is substantial respiratory acidosis with an arterial pH of

Figure 4-16 Gas exchange during changes in ventilation. With hypoventilation, note the relatively large rise in PCO₂ and consequent fall in pH compared with the modest fall in arterial oxygen saturation. (Redrawn from West JB: *Pulmonary physiology—the essentials*, ed 8, Baltimore, 2013, Lippincott Williams & Wilkins.)

approximately 7.2. This fact emphasizes again that the hypoxemia is usually not as important as the carbon dioxide retention and respiratory acidosis in pure hypoventilation.

A feature of alveolar hypoventilation is that, although the arterial PCO_2 is always raised, the arterial PO_2 may be returned to normal very easily by giving supplementary oxygen. Suppose that the patient with barbiturate intoxication just discussed is given 30% oxygen to breathe. If we assume that the ventilation remains unchanged, it can be shown (from Equation 20) that the alveolar PO_2 rises from 74 to approximately 140 mm Hg. Thus a relatively small increase in inspired PO_2 is very effective in eliminating the arterial hypoxemia of hypoventilation.

Diffusion Limitation

It is now generally believed that oxygen, carbon dioxide, and indeed all gases cross the blood-gas barrier by simple passive diffusion. Fick's law of diffusion states that the rate of transfer of a gas through a sheet of tissue is proportional to the tissue area (A) and the difference in partial pressure ($P_1 - P_2$) between the two sides, and is inversely proportional to the thickness (T):

$$\dot{V}_{\text{gas}} = \frac{A}{T} \times D \times (P_1 - P_2) \quad [21]$$

As we have seen already, the area of the blood-gas barrier in the lung is enormous (50 to 100 m^2), and the thickness is less than 0.3 μm in some places, so the dimensions of the barrier are ideal for diffusion.

The rate of diffusion is also proportional to a constant (D), which depends on the properties of the tissue and the particular gas. The constant is proportional to the solubility (Sol) of the gas, and inversely proportional to the square root of the molecular weight (MW):

$$D \propto \frac{\text{Sol}}{\sqrt{\text{MW}}} \quad [22]$$

This means that, per the millimeters of mercury difference between capillary and alveolar partial pressures, carbon dioxide diffuses approximately 20 times more rapidly than oxygen through tissue sheets, because carbon dioxide has a much higher solubility (24:1 at 37° C), but the square roots of the molecular weights are not very different (1.17:1). Note that this calculation applies only to tissue sheets and does not fully account for the uptake of oxygen or output of carbon dioxide by the lung, because the chemical reactions between these gases and components of blood also play a role (see later discussion).

Oxygen Uptake along the Pulmonary Capillary

Figure 4-17 shows calculated changes in the PO_2 of the blood along the pulmonary capillary as oxygen is taken up under normal conditions. The calculation is based on Fick's law of diffusion (see Equation 21). One of the several assumptions is that the diffusion characteristics of the blood-gas barrier are uniform along the length of the capillary. The calculation is complicated by the fact that the change in the PO_2 of the capillary blood depends on the oxygen dissociation curve. This is not only nonlinear but is also influenced by the simultaneous elimination of carbon dioxide. The calculation is often known as the Bohr integration because it was first carried out in a simplified form by

Figure 4-17 Typical time courses for the change in PO_2 in the pulmonary capillary when diffusion is normal, when the contact time is reduced, and when the blood-gas barrier is abnormally thick. The time course for carbon monoxide uptake is also shown. (Redrawn from West JB: *Pulmonary physiology—the essentials*, ed 8, Baltimore, 2013, Lippincott Williams & Wilkins.)

Christian Bohr.⁸⁰ Modern computations take into account reaction times of oxygen with hemoglobin and also reaction rates associated with carbon dioxide elimination (see later discussion).⁸¹

Figure 4-17 shows that the time spent by the blood in the pulmonary capillary under normal resting conditions is approximately 0.75 second. This number is obtained by dividing the volume of blood calculated to be in the pulmonary capillaries (75 mL) by the cardiac output (6 L/min).⁸² The figure shows that the PO_2 of pulmonary capillary blood very nearly reaches that of alveolar gas after approximately a third of the available time in the capillary. This means that there is normally ample time for essentially complete oxygenation of the blood or, as it is sometimes said, the normal lung has substantial diffusion “reserves.”

If the blood-gas barrier is thickened, the rate of transfer of oxygen across the barrier is reduced in accordance with Fick's law, and the rate of rise of PO_2 is slower, as shown in Figure 4-17. Under these circumstances a PO_2 difference between alveolar gas and end-capillary blood may develop. This means that there is some diffusion limitation of oxygen transfer. It is important to appreciate that under most conditions at sea level oxygen transfer is perfusion limited and only under unusual conditions such as severe interstitial lung disease is there some diffusion limitation. However, at high altitude, diffusion limitation during exercise is universal, even in health. In well-trained athletes, diffusion may be limiting even at sea level.

It can be shown⁸³ that whether diffusive transfer of any gas is perfusion or diffusion limited depends on the ratio of D , the diffusive conductance of the blood-gas barrier, to the product of the solubility of the gas in blood (commonly referred to as β) and the total pulmonary blood flow

Figure 4-18 Diffusion-limited transfer of various gases in the lung. Diffusion limitation (L_{diff}) is on a scale of 0 (no limitation) to 1 (complete limitation) (see text for details). (From Scheid P, Piiper J: Blood gas equilibration in lungs and pulmonary diffusing capacity. In Chang HK, Paiva M, editors: *Respiratory physiology: An analytical approach*, New York, 1989, Marcel Dekker, pp 453–497.)

rate (\dot{Q}): $D/(\dot{Q}\beta)$. For oxygen, β refers to the slope of the oxygen-hemoglobin dissociation curve. Diffusive equilibration is more likely the higher the $D/(\dot{Q}\beta)$ ratio.

It is clear that for oxygen the slope of the blood dissociation curve is not a constant, which makes this ratio difficult to apply. It depends on the P_{O_2} and also to a lesser extent on factors that shift the dissociation curve, such as pH, PCO_2 , temperature, and red cell 2,3-DPG concentration. Under hypoxic conditions, when the lung is operating on the lower, steeper part of the oxygen dissociation curve, β is much greater than in normoxia when arterial P_{O_2} is on the flat portion of the curve, and the ratio is thus lower. This explains why diffusion limitation for oxygen, unusual at sea level, is common at high altitude. Figure 4-18 shows the extent to which perfusion and diffusion limit the transfer of gas under various conditions.⁸³ Although the figure is based on a number of simplifying assumptions, it is conceptually valuable.

Note that physiologically inert gases such as nitrogen and sulfur hexafluoride (right-hand end of Fig. 4-18) are completely perfusion limited in their transfer. (*Physiologically inert* means that, being carried in blood only in physical solution, their blood concentration is directly proportional to partial pressure; that is, they obey Henry's law of solubility.) The same perfusion limitation applies to oxygen in hyperoxia because, high on the dissociation curve, the value of β is very low so that $(D/\dot{Q}\beta)$ is very high and diffusion limitation is not seen. However, oxygen transfer under conditions of hypoxia can be partly diffusion limited because the lung is working low on the dissociation curve, where the slope (β) is much higher than normal. This is particularly the case for oxygen transfer during hypoxic exercise and explains why diffusion is limiting in the normal lung during maximal exercise at extreme high altitude, even in well-acclimatized subjects.^{84,85} On the summit of Mount Everest, there is apparently diffusion limitation even at rest.

Figure 4-18 also shows that the transfer of carbon monoxide by the lung is markedly diffusion limited. This follows from the very steep slope of the dissociation curve of carbon monoxide with blood (that is, β is very large). Another way

of looking at this is to say that the avidity of hemoglobin for carbon monoxide is so high that the partial pressure in the blood hardly rises along the pulmonary capillary (see Fig. 4-17). Under these conditions it is intuitively clear that the amount of carbon monoxide that is taken up depends almost entirely on the diffusion properties of the blood-gas barrier, explaining why this gas is so well suited to measuring the lung's diffusing capacity.

Reaction Rates with Hemoglobin

When oxygen (or carbon monoxide) is added to blood, its combination with hemoglobin is quite fast, being close to completion in 0.2 second. Such reaction rates can be measured using special equipment in which reduced hemoglobin and dissolved oxygen are rapidly mixed and the rate of formation of oxyhemoglobin is measured photometrically. Although hemoglobin is oxygenated rapidly within the pulmonary capillary, even this rapid reaction significantly delays the loading of oxygen by the red cell.

The transfer of oxygen from the alveolar gas to its combination with hemoglobin in the red cell can therefore be regarded in two stages: (1) diffusion of oxygen through the blood-gas barrier, including the plasma and red cell interior; and (2) reaction of the oxygen with hemoglobin (Fig. 4-19A). Although at first sight these two processes are very different, it is possible to treat them mathematically in a similar way and to regard each as contributing its own "resistance" to the transfer of oxygen. Such an analysis was carried out by Roughton and Forster,⁸⁶ who showed that the following relationship exists:

$$\frac{1}{DL} = \frac{1}{DM} + \frac{1}{(\theta \times Vc)} \quad [23]$$

where DL refers to the diffusing capacity of the lung, DM is the diffusing capacity of the membrane (which includes the plasma and red cell interior), θ is the rate of reaction of oxygen (or carbon monoxide) with hemoglobin (expressed per milliliter of blood), and Vc is the volume of blood in the pulmonary capillaries.

In the normal lung the resistances offered by the membrane and blood reaction components are approximately equal. This means that, if the capillary blood volume is reduced by disease, the measured diffusing capacity of the lung is lowered. In fact, the equation can be used to separate the two components. To do this, the diffusing capacity is measured at both high and normal alveolar P_{O_2} values. Increasing the alveolar P_{O_2} reduces the value of θ for carbon monoxide because the carbon monoxide has to compete with a high pressure of oxygen for the hemoglobin. If the resulting measurements of $1/DL$ are plotted against $1/\theta$, as shown in Figure 4-19B, the slope of the line is $1/Vc$, whereas the intercept on the vertical axis is $1/DM$.

Diffusing Capacity

Carbon monoxide is usually the gas of choice for measuring the diffusion properties of the lung because, as Figure 4-18 shows, its transfer is almost entirely diffusion limited. It is true that part of the limitation has to do with the rate of reaction of carbon monoxide with hemoglobin (see Fig. 4-19A), but this is conveniently included in the measurement of diffusion properties. Although it could be argued that we are really more interested in oxygen and the effects

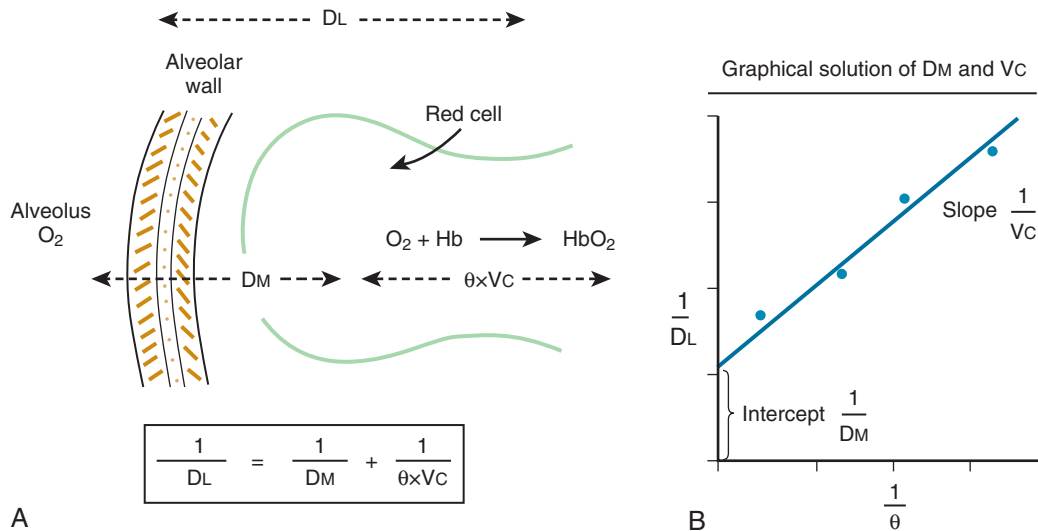

Figure 4-19 **A**, The two components of the measured diffusing capacity (DL) of the lung: that due to the diffusion process itself (DM) and that attributable to the time taken for oxygen (or carbon monoxide) to react with hemoglobin (Hb) ($\theta \times VC$). **B**, $1/DL$ plotted against $1/\theta$ can be used to derive DM and VC, vital capacity.

of any diffusion limitation on this gas, oxygen uptake is typically perfusion limited under normoxic conditions (see Fig. 4-18) and partly perfusion and diffusion limited under hypoxic conditions. For this reason, measurements using oxygen are often difficult to interpret, although techniques using isotopes of oxygen have been proposed.⁸³ However, for the measurement of diffusion properties in the pulmonary function laboratory, carbon monoxide is the best gas.

As indicated earlier, Fick's law states that the amount of gas transferred across a tissue sheet is proportional to the area, a diffusion constant, and the difference in partial pressure, and is inversely proportional to the thickness:

$$\dot{V}_{\text{gas}} = \frac{A}{T} \times D \times (P_1 - P_2) \quad [21]$$

The actual lung is so complex that it is not possible to determine the area and the thickness of the blood-gas barrier during life. Instead, the equation is written to combine the factors A, T, and D into one constant, DL, as follows:

$$\dot{V}_{\text{gas}} = DL \times (P_1 - P_2) \quad [24]$$

where DL is called the diffusing capacity of the lung and consequently includes the area, thickness, and diffusion properties of the tissue sheet, as well as the properties of the diffusing gas. Thus the diffusing capacity for carbon monoxide is given by:

$$DL = \frac{\dot{V}_{\text{CO}}}{(P_1 - P_2)} \quad [25]$$

where P_1 and P_2 are the partial pressures of carbon monoxide in alveolar gas and capillary blood, respectively. Because the partial pressure of carbon monoxide in capillary blood is so small (see Fig. 4-17), it can generally be neglected. In this case, the equation becomes:

$$DL = \frac{\dot{V}_{\text{CO}}}{P_{\text{ACO}}} \quad [26]$$

or, in words, the diffusing capacity of the lung for carbon monoxide is the volume of carbon monoxide transferred in

milliliters per minute per millimeters of mercury of alveolar partial pressure of carbon monoxide.

Some people, for example, cigarette smokers, have sufficient carboxyhemoglobin in their blood that the partial pressure of carbon monoxide in the pulmonary capillaries cannot be neglected. In this case, an estimate of the partial pressure of carbon monoxide in pulmonary capillary blood can be made using a rebreathing technique, and Equation 25 is then used to determine diffusing capacity.

Several techniques are available for measuring the diffusing capacity of the lung for carbon monoxide. In the *single-breath method*, a single inspiration of a dilute mixture (approximately 0.3%) of carbon monoxide is made, and the rate of disappearance of carbon monoxide from the alveolar gas during a 10-second breath-hold is calculated. This is usually done by measuring the inspired and expired concentrations of carbon monoxide with an infrared analyzer. Alternatively, a respiratory mass spectrometer can be used if ¹⁸O-labeled carbon monoxide is employed. At the end of the breath-holding period, a post-dead space sample of alveolar gas is obtained by discarding the first 750 mL of the expiration. The alveolar concentration of carbon monoxide is not constant during the breath-holding period, but allowance can be made, assuming that the disappearance of carbon monoxide follows an exponential law. Helium (or methane) is also added to the inspired gas to give a measurement of lung volume by dilution. The appropriate equation is:

$$DL = \frac{\dot{V}_A \times K}{t} \log_e \left[\frac{F_{\text{ICO}} \times F_{\text{AHe}}}{F_{\text{IHe}} \times F_{\text{ACO}_2}} \right] \quad [27]$$

where \dot{V}_A is the alveolar volume in liters, t is breath-holding time in seconds, K is a constant, and the fractional concentrations of carbon monoxide and helium in inspired and expired gas are as indicated. Further details of this method, which requires considerable care for accurate results, can be found in more specialized texts.⁸⁷

The diffusing capacity can also be measured using the steady-state method. The subject breathes a low

concentration of carbon monoxide (approximately 0.1%) for 0.5 minute or so, until a steady state of gas exchange has been reached. The constant rate of disappearance of carbon monoxide from alveolar gas is then measured for a further short period, along with the alveolar concentration. This technique is better suited to measurements during exercise in which breath-holding becomes a problem. The normal value of the diffusing capacity for carbon monoxide depends on age, sex, and height (as is the case for most pulmonary function tests), and appropriate regression equations are available.⁸⁷ Experiments comparing measured arterial PO_2 with that predicted for a given degree of ventilation-perfusion mismatching (see later) without any diffusion limitation agree until the actual diffusing capacity decreases by 50%.⁸⁸ This emphasizes the large safety factor in the normal lung before hypoxemia results from a diffusion limitation.

As Figure 4-19A indicates, the uptake of carbon monoxide is determined by the diffusion properties of the blood-gas barrier (including plasma and red cell interior) and the rate of combination of carbon monoxide with blood. The *diffusion properties* of the alveolar membrane depend on its thickness and area. Thus the diffusing capacity is reduced by diseases in which the thickness is increased, including diffuse interstitial pulmonary fibrosis, asbestosis, and sarcoidosis. It is also reduced when the area is decreased, for example, by pneumonectomy. The diffusing capacity in emphysema may fall because of the loss of alveolar walls and capillaries, but also perhaps because of the unevenness of ventilation and diffusion (see later discussion).

The *rate of combination* of carbon monoxide with blood is reduced whenever the number of red cells in the capillaries is reduced. This happens in anemia and also in diseases that may reduce the capillary blood volume in certain regions of the lung, such as pulmonary embolism.

Figure 4-19B shows how it is possible to separate the membrane and blood components of the diffusing capacity by making measurements at high and normal values of alveolar PO_2 . However, this is only possible in subjects with nearly normal lungs. In many patients in whom the measured diffusing capacity is low, the interpretation is uncertain. The reason for this is the unevenness of ventilation and diffusion properties throughout the diseased lung. Such lungs tend to empty unevenly, with the result that the post-dead space sample of expired gas that is analyzed for carbon monoxide is not representative of the whole lung. Partly as a consequence of this, different methods of measuring diffusing capacity in patients with diseased lungs frequently give very different results. For this reason the diffusing capacity is sometimes referred to as the *transfer factor* (especially in Europe) to emphasize that it is more a measure of the lung's overall ability to transfer carbon monoxide into the blood than a specific test of diffusion characteristics. Nevertheless, the test gives considerable information in the nearly normal lung, and, even in patients with severe disease, the results are empirically useful for assessing the severity and type of lung disease in the pulmonary function laboratory. (For a discussion of clinical tests, see Chapter 25).

Shunt

Shunt refers to the entry of blood into the systemic arterial system without going through ventilated areas of lung.

Even the normal cardiopulmonary system shows some depression of the arterial PO_2 as a result of this factor. For example, in the normal lung some of the bronchial artery blood is collected by the pulmonary veins after it has perfused the bronchi. Because the oxygen concentration of this blood has been reduced, its addition to the normal end-capillary blood results in a reduction of arterial PO_2 . Another source is a small amount of coronary venous blood that drains directly into the cavity of the left ventricle through the thebesian veins. Of course, most of the coronary venous blood ends up in the coronary sinus, and only a minute fraction reaches the left ventricle directly. Such shunts depress arterial PO_2 only by approximately 1 to 2 mm Hg.

In patients with congenital heart disease, there may be a direct addition of venous blood to arterial blood across a defect between the right and left sides of the heart. Generally this is associated with some increase in pressure on the right side; otherwise, the shunt is only from left to right. In lung disease there may be gas-exchanging units that are completely unventilated because of airway obstruction, atelectasis, or alveolar filling with fluid or cells. The blood draining from these constitutes a shunt. It could be argued that such units are simply at the extreme end of the spectrum of ventilation-perfusion inequality (see next section), but the gas-exchange properties of unventilated units are so different (e.g., during oxygen breathing) that it is convenient to separate them.

When the shunt is caused by the addition of mixed venous blood (pulmonary arterial) to blood draining from the capillaries (pulmonary venous), it is possible to calculate the amount of shunt flow. This is done using a mixing equation. The total amount of oxygen delivered into the systemic circulation per minute is the total blood flow (\dot{Q}_T) multiplied by the oxygen concentration in the systemic arterial blood (Ca_{O_2}), or $\dot{Q}_T \times Ca_{O_2}$. This must equal the sum of the amounts of oxygen in the shunted blood ($\dot{Q}_s \times C\bar{v}O_2$) and the nonshunted or end-capillary blood [$(\dot{Q}_T - \dot{Q}_s) \times Cc'O_2$]. Also, it is assumed that all regions of lung not subject to shunt are normal. Thus

$$\dot{Q}_T \times Ca_{O_2} = (\dot{Q}_s \times C\bar{v}O_2) + (\dot{Q}_T - \dot{Q}_s) \times Cc'O_2 \quad [28]$$

Rearranging, this gives

$$\frac{\dot{Q}_s}{\dot{Q}_T} = \frac{(Cc'O_2 - Ca_{O_2})}{(Cc'O_2 - C\bar{v}O_2)} \quad [29]$$

The oxygen concentration of end-capillary blood is usually calculated from the alveolar PO_2 and the hemoglobin concentration, assuming 100% oxyhemoglobin saturation (hence the assumption of normalcy of all regions not subject to shunt).

When the shunt is caused by blood that does not have the same oxygen concentration as mixed venous blood (e.g., bronchial venous blood), it is generally not possible to calculate its true magnitude. However, it is often useful to calculate an "as if" shunt, that is, what the shunt *would* be if the observed depression of arterial oxygen concentration were caused by the addition of mixed venous blood. An analogous procedure is frequently used to quantitate the degree of hypoxemia caused by ventilation-perfusion inequality, although it is clearly recognized in this case that there may be relatively little or even no blood flow to completely unventilated lung units.

An important diagnostic feature of a shunt is that the arterial PO_2 does not rise to the normal level (which in theory should be 670 mm Hg) when the patient is given 100% oxygen to breathe. The reason for this is that the shunted blood that bypasses ventilated alveoli is never exposed to the higher alveolar PO_2 . Its addition to end-capillary blood therefore continues to depress the arterial PO_2 . Nevertheless, the arterial PO_2 is elevated somewhat because of the oxygen added to the capillary blood of the ventilated lung. Most of this added oxygen is in the dissolved form rather than attached to hemoglobin because the blood that is perfusing lung regions with normal ventilation-perfusion ratios (see later) is normally nearly fully saturated.

The administration of 100% oxygen to a patient with a shunt is a very sensitive method of detecting small amounts of shunting. This is because when the arterial PO_2 is very high, a very small reduction of arterial oxygen concentration caused by the addition of the shunted blood causes a relatively large fall in PO_2 . This is directly attributable to the almost flat slope of the oxygen dissociation curve in this region.

A patient with a shunt usually does not have an increased PCO_2 in the arterial blood in spite of the fact that the shunted blood is rich in carbon dioxide. The reason is that the chemoreceptors sense any elevation of arterial PCO_2 and respond by increasing the ventilation. As a consequence, the PCO_2 of the unshunted blood is reduced by the hyperventilation until the arterial PCO_2 is back to normal. Indeed, in some patients with large shunts caused, for example, by cyanotic congenital heart disease, the arterial PCO_2 is low because the arterial hypoxemia increases the respiratory drive.

Ventilation-Perfusion Relationships

It has been known for many years that mismatching of ventilation and blood flow is the most common cause of hypoxemia in lung disease. Uneven ventilation and blood flow are also a cause of carbon dioxide retention. Early intimations of the importance of the subject go back to Krogh and Lindhard⁸⁹ and Haldane.⁹⁰ However, our understanding advanced in the late 1940s when Fenn and colleagues⁹¹ and Riley and Courmand⁹² introduced graphic analysis of gas exchange. This was an important advance because the interrelationships of ventilation, blood flow, and gas exchange depend on the oxygen and carbon dioxide dissociation curves, which are not only nonlinear but interdependent, and direct solutions to the gas exchange equations that relate the ventilation-perfusion ratio to gas exchange (see later, Equations 31 and 32) are not possible.

A more recent phase began with the use of computers to describe the oxygen and carbon dioxide dissociation curves.^{93,94} These procedures enabled investigators to answer questions about gas exchange that had been impossibly difficult before that time. The behavior of distributions of ventilation-perfusion ratios was analyzed,⁹⁵ and Wagner and colleagues⁹⁶ introduced the multiple inert gas elimination technique, which allowed, for the first time, information about the dispersion, number of modes, and shape of the distributions of ventilation, of perfusion, and of their ratio to be obtained.

Gas Exchange in a Single Lung Unit

The PO_2 , PCO_2 , and PN_2 in any gas-exchanging unit of the lung are uniquely determined by three major factors: (1) the ventilation-perfusion ratio, (2) the composition of the inspired gas and the composition of the mixed venous blood, and (3) the slopes and positions of the relevant blood-gas dissociation curves.

Formally, the key role of the ventilation-perfusion ratio can be derived as follows. The amount of carbon dioxide exhaled into the air from alveolar gas per minute is given by Equation 5:

$$\dot{V}CO_2 = \dot{V}_A \times PACO_2 / K \quad [5]$$

where $\dot{V}CO_2$ is the carbon dioxide output, \dot{V}_A is the alveolar ventilation, K is a constant, and there is no carbon dioxide in the inspired gas.

The amount of carbon dioxide lost into alveolar gas from capillary blood per minute is given by:

$$\dot{V}CO_2 = \dot{Q}(C\bar{V}CO_2 - Cc'CO_2) \quad [30]$$

where \dot{Q} is blood flow, and $C\bar{V}CO_2$ and $Cc'CO_2$ are the concentrations of carbon dioxide in mixed venous and end-capillary blood, respectively. Now, in a steady state, the amount of carbon dioxide lost from the alveoli and from the capillary blood must be the same. Therefore:

$$\begin{aligned} \dot{V}_A \times PACO_2 \times K &= \dot{Q}(C\bar{V}CO_2 - Cc'CO_2) \text{ or} \\ \frac{\dot{V}_A}{\dot{Q}} &= \frac{(C\bar{V}CO_2 - Cc'CO_2)}{PACO_2} \times K \end{aligned} \quad [31]$$

Thus the alveolar PCO_2 and the corresponding end-capillary carbon dioxide concentration (assuming end-capillary and alveolar PCO_2 are identical) are determined by (1) the ventilation-perfusion ratio, (2) the mixed venous carbon dioxide concentration, and (3) the carbon dioxide dissociation curve relating PCO_2 to carbon dioxide concentration.

Although this equation looks simple, its appearance is deceptive because, when the ventilation-perfusion ratio increases (for example), the alveolar PO_2 rises. This means that the oxygen saturation of the blood increases and therefore that the relationship between PCO_2 and carbon dioxide concentration is altered. Thus the alveolar PO_2 is an implicit variable in the equation. In addition, the relationship between PCO_2 and carbon dioxide concentration is nonlinear. This is the reason that it was possible to solve the equation only graphically until the introduction of computers.

Just as, in the context of the alveolar ventilation equation (see “Hypoventilation” earlier), both oxygen and carbon dioxide exchange were able to be expressed in equations of similar form, it is possible to write an equation similar to Equation 31 for oxygen exchange based on the same principles as applied for carbon dioxide. Again, the approximation is made that inspired alveolar ventilation (\dot{V}_I) equals expired alveolar ventilation (\dot{V}_A) to keep the equation simple, but, as for the alveolar gas equation, the fact that \dot{V}_I and \dot{V}_A are generally not quite the same can formally be taken into account. Using this approximation, the equation for oxygen is

$$\frac{\dot{V}_A}{\dot{Q}} = K \times \frac{(Cc'O_2 - C\bar{V}O_2)}{(PIO_2 - PAO_2)} \quad [32]$$

Figure 4-20 Oxygen-carbon dioxide diagram shows how the PO_2 and PCO_2 of a lung unit alter as the ventilation-perfusion ratio (\dot{V}_A/\dot{Q}) is changed. I, inspired gas; \bar{v} , mixed venous blood. (Redrawn from West JB: *Respiratory physiology—the essentials*, ed 9, Baltimore, 2012, Lippincott Williams & Wilkins.)

Just as for carbon dioxide, the alveolar and end-capillary PO_2 values are taken to be identical, implying diffusion equilibrium across the blood-gas barrier. It is seen that the determinants of alveolar PO_2 , as for carbon dioxide, are threefold: (1) the ventilation-perfusion ratio, (2) inspired and mixed venous oxygen levels, and (3) the relationship between PO_2 and oxygen concentration (i.e., the oxygen dissociation curve).

Graphic analysis of these relationships is assisted by the use of the oxygen-carbon dioxide diagram, in which PO_2 is on the horizontal axis and PCO_2 is on the vertical axis. This diagram has been used to solve many problems related to ventilation-perfusion relationships.⁹⁷ A simple introduction to the diagram is given elsewhere.⁹⁸ It shows the solutions to Equations 31 and 32 for each value of the ventilation-perfusion ratio from zero (unventilated lung) to infinity (unperfused lung).

Figure 4-20 is an example of the use of the oxygen-carbon dioxide diagram to show how the PO_2 and PCO_2 of a lung unit change as the ventilation-perfusion ratio is either decreased below or increased above the normal value. Note that for a given composition of inspired gas (I) and mixed venous blood (\bar{v}), the possible combinations of PO_2 and PCO_2 are constrained to a single line known as the ventilation-perfusion ratio line. Each point on that line uniquely corresponds to a value of the ventilation-perfusion ratio. Note also that, at the extremes of the spectrum of ventilation-perfusion ratios, the PO_2 and PCO_2 of end-capillary blood are those of mixed venous blood when the ventilation-perfusion ratio is zero, and the PO_2 and PCO_2 of alveolar gas are the same as those of inspired gas for a ventilation-perfusion ratio of infinity. In this diagram and in the rest of this section, we assume that there is complete diffusion equilibration between the PO_2 and PCO_2 of alveolar gas and end-capillary blood. This is a reasonable assumption unless there is marked thickening of the blood-gas barrier or one is considering a subject exercising in hypoxia.

Figure 4-21 shows the PO_2 , PCO_2 , and oxygen concentration of end-capillary blood of a lung unit as its ventilation-perfusion ratio is increased from extremely low to extremely high values. The lung is assumed to be breathing air, the PO_2 and PCO_2 of mixed venous blood are normal (40 and 45 mm Hg, respectively), and the hemoglobin concentration is 14.8 g/100 mL. The normal value of the ventilation-

Figure 4-21 Changes in PO_2 , PCO_2 , and end-capillary oxygen content in a lung unit are shown as its ventilation-perfusion ratio is altered. See text for assumptions. (Redrawn from West JB: *State of the art: ventilation-perfusion relationships*. *Am Rev Respir Dis* 116:919–943, 1977.)

perfusion ratio is in the range of 0.8 to 1. Note that as the ratio is altered either above or below that value, the PO_2 changes considerably. By contrast, the oxygen concentration increases little as the ventilation-perfusion ratio is raised above the normal value because the hemoglobin is normally almost fully saturated. The PCO_2 falls considerably as the ventilation-perfusion ratio is raised, but rises relatively little at lower ventilation-perfusion ratio values. The quantitative information in this figure is consistent with the graphic analysis of Figure 4-20.

Pattern in the Normal Lung

Both ventilation and perfusion vary throughout the lung. It is thus instructive to look at the topographic inequality of gas exchange in the normal upright lung as a result of ventilation-perfusion inequality. We saw previously that both ventilation and blood flow per unit volume decrease from the bottom to the top of the upright lung. However, the changes for blood flow are more marked than those for ventilation. As a consequence, the ventilation-perfusion ratio increases from low values at the base to high values at the apex of the normal upright lung (Fig. 4-22).

Because the ventilation-perfusion ratio determines the gas exchange in any region (Equations 31 and 32), the corresponding pattern of variation in PO_2 and PCO_2 in the lung can be calculated. Normal composition of mixed venous blood is here assumed. Note that the PO_2 increases by some 40 mm Hg from base to apex, whereas the PCO_2 falls by 14 mm Hg. The pH is high at the apex because the PCO_2 there is low (the base excess is the same throughout the lung). Very little of the total oxygen uptake occurs at the apex, principally because the blood flow there is very low.

Figure 4-22 also helps to explain why ventilation-perfusion inequality interferes with overall gas exchange. Note that the base of the lung has most of the blood flow, but the PO_2 and oxygen concentration of the end-capillary blood are lowest there. As a result, the effluent pulmonary venous blood (which becomes the systemic arterial blood) is loaded with moderately oxygenated blood from the base. The net result is a depression of the arterial PO_2 below that which would be seen if ventilation and blood flow were uniformly distributed.

Figure 4-22 Regional differences of gas exchange down the upright normal lung. The lung is divided into nine imaginary slices. \dot{Q} , blood flow; \dot{V}_A , alveolar ventilation. (Redrawn from West JB: *Respiratory physiology—the essentials*, ed 9, Baltimore, 2012, Lippincott Williams & Wilkins.)

The same argument applies to carbon dioxide. In this case the PCO_2 and carbon dioxide concentrations of the end-capillary blood are highest at the base, where the blood flow is greatest. As a result, the PCO_2 of arterial blood is elevated above that which would be seen if there were no ventilation-perfusion inequality. In other words, a lung with mismatched ventilation and blood flow is inefficient at exchanging gas, be this oxygen or carbon dioxide. In fact, the inefficiency applies to any gas that is being transferred by the lung. The extent of the impairment of gas exchange caused by any given amount of ventilation-perfusion inequality depends mostly on the solubility, or slope of the blood dissociation curve, of the gas. For example, in a log-normal distribution of ventilation-perfusion ratios, gases with medium solubility experience the greatest interference with pulmonary transfer.⁹⁹ In the normal lung the effect of inequality due to gravity on arterial PO_2 can be modeled, as shown in Figure 4-22. The overall effect of such ventilation-perfusion inequality on gas exchange is very small, reducing arterial PO_2 by only approximately 4 mm Hg from that in a homogeneous lung.

Traditional Assessment of Ventilation-Perfusion Inequality

A central question that has engaged the attention of physiologists and physicians for many years has been how best to assess the amount of ventilation-perfusion inequality. Ideally, we would like to know the actual distribution of ventilation-perfusion ratios (see next section), but the procedure required for this is too complicated for many clinical situations. Traditionally we rely on measurements of PO_2 and PCO_2 in arterial blood and expired gas.

The arterial PO_2 certainly gives some information about the degree of ventilation-perfusion inequality. In general, the lower the PO_2 , the more marked is the mismatching of ventilation and blood flow. The chief merit of this measurement is its simplicity, but a disadvantage is that its value is sensitive to the overall ventilation and pulmonary blood flow, to inspired PO_2 , and to other potential causes of hypoxemia already discussed.

Figure 4-23 Oxygen-carbon dioxide diagram showing the ideal point (i) and the points for arterial blood (a) and alveolar gas (A) (see text for details). I, inspired gas; \dot{Q} , blood flow; R, respiratory exchange ratio; \bar{V} , mixed venous blood; \dot{V}_A , ventilation. (Redrawn from West JB: *Respiratory physiology—the essentials*, ed 9, Baltimore, 2012, Lippincott Williams & Wilkins.)

Arterial PCO_2 is so sensitive to the level of ventilation that it gives little information about the extent of the ventilation-perfusion inequality. However, the most common cause of an increased PCO_2 in chronic lung disease is mismatching of ventilation and blood flow as explained later in the section on ventilation-perfusion inequality and carbon dioxide retention.

Because of these limitations, the alveolar-arterial PO_2 difference is frequently measured and is more informative than the arterial PO_2 alone because it is less sensitive to the level of overall ventilation. To understand the significance of this measurement, we need to look in more detail at how gas exchange is altered by the imposition of ventilation-perfusion inequality.

Figure 4-23 shows an oxygen-carbon dioxide diagram with the same ventilation-perfusion line as that in Figure 4-20. Suppose initially that this lung has no ventilation-perfusion inequality. The PO_2 and PCO_2 of the alveolar gas and arterial blood would then be represented by point i, known as the ideal point. This is at the intersection of the gas and blood respiratory exchange ratio (R) lines; these are the lines that indicate the possible compositions of alveolar gas and arterial blood that are consistent with the overall respiratory exchange ratio (carbon dioxide output/oxygen uptake) of the whole lung. In other words, a lung in which $R = 0.8$ would have to have its mixed alveolar gas point (A) located somewhere on the line joining points i and I. A similar statement can be made for the arterial gas point (a).

What happens to the composition of mixed alveolar gas and arterial blood as ventilation-perfusion inequality is imposed on the lung? The answer is that both points diverge away from the ideal point (i), along the gas and blood R lines. The more extreme the degree of ventilation-perfusion inequality, the further the divergence. Moreover, the type of ventilation-perfusion inequality determines how much each point will move. For example, a distribution containing a large amount of ventilation to units with high ventilation-perfusion ratio especially moves point A down and to the right away from point i. By the same token, a distribution containing large amounts of blood flow to units with low ventilation-perfusion ratios predominantly moves point a leftward along the blood R line.

It is clear that the horizontal distance between points A and a (i.e., the mixed alveolar-arterial PO_2 difference) would be a useful measure of the degree of ventilation-perfusion inequality. Unfortunately, this index is impossible to obtain in most patients because A denotes the composition of *mixed* expired gas, excluding the anatomic dead space gas. In most diseased lungs, the alveoli empty sequentially, with poorly ventilated alveoli emptying last, so that a post-dead space sample is not representative of all mixed expired alveolar gas. In a few patients who have essentially uniform ventilation but uneven blood flow, this index can be used, and it is occasionally reported in patients with pulmonary embolism. In this instance, the PO_2 of end-tidal gas is taken to represent mixed expired alveolar gas.

Because the mixed expired alveolar PO_2 is usually impossible to obtain, a more useful index is the PO_2 difference between ideal alveolar gas and arterial blood, that is, the horizontal distance between points i and a. The ideal alveolar PO_2 is calculated from the alveolar gas equation:

$$PAO_2 = PIO_2 - \frac{PACO_2}{R} + \left[PACO_2 \times FIO_2 \times \frac{(1-R)}{R} \right] \quad [20]$$

To use this equation, we assume that the PCO_2 of ideal alveolar gas is the same as the PCO_2 of arterial blood. The rationale for this is that the line along which point a moves (in Fig. 4-23) is so nearly horizontal that the value is close enough for clinical purposes. It is important to note that this ideal alveolar-arterial PO_2 difference is caused by units situated on the ventilation-perfusion ratio line between points i and \bar{v} , that is, units with abnormally low ventilation-perfusion ratios. This means that a diseased lung may have substantial ventilation-perfusion inequality but a nearly normal ideal alveolar-arterial PO_2 difference if most of the inequality is caused by units with abnormally high ventilation-perfusion ratios.

Physiologic shunt is another useful index of ventilation-perfusion inequality. It measures that movement of the arterial point away from the ideal point along the blood R line (see Fig. 4-23). It is therefore caused by blood flow to lung units with abnormally low ventilation-perfusion ratios. To calculate physiologic shunt, we pretend that all of the leftward movement of the arterial point a is caused by the addition of mixed venous blood \bar{v} to ideal blood i. This is not so unreasonable as it might at first seem because units with very low ventilation-perfusion ratios put out blood that has essentially the same composition as that of mixed venous blood (see Figs. 4-20 and 4-21). The shunt equation is used in the following form:

$$\frac{\dot{Q}_{PS}}{\dot{Q}_T} = \frac{(CiO_2 - CaO_2)}{(CiO_2 - C\bar{v}O_2)} \quad [33]$$

where \dot{Q}_{PS} refers to physiologic shunt, \dot{Q}_T refers to total blood flow through the lung, and CiO_2 , CaO_2 , and $C\bar{v}O_2$, refer to the oxygen concentrations of ideal, arterial, and mixed venous blood, respectively. The oxygen concentration of ideal blood is calculated from the ideal PO_2 and the oxygen dissociation curve. The normal value for *physiologic shunt* is less than 0.05.

The last traditional index to be discussed is *physiologic dead space* (also known as wasted ventilation). Whereas physiologic shunt reflects the amount of blood flow going to lung units with abnormally low ventilation-perfusion

ratios, physiologic dead space is a measure of the amount of ventilation going to units with abnormally high ventilation-perfusion ratios. Thus the two indices provide measurements of both ends of the spectrum of ventilation-perfusion ratios.

To calculate physiologic dead space, we pretend that all the movement of the alveolar point A away from the ideal point i (see Fig. 4-23) is caused by the addition of inspired gas I to ideal gas. Again, this is not so unreasonable as it may first appear, because units with very high ventilation-perfusion ratios behave very much like point I (see Fig. 4-23). Because, as indicated earlier, it is usually impossible to obtain a pure sample of mixed expired gas, we generally collect mixed expired gas and measure its composition, E. The mixed expired gas contains a component from anatomic dead space, which therefore moves its composition further toward point I. The Bohr equation (Equation 9) is then used in the form

$$\frac{VD_{phys}}{VT} = \frac{(PACO_2 - PECO_2)}{PACO_2} \quad [34]$$

where VD_{phys} is physiologic dead space, VT is tidal volume, and $PECO_2$ is mixed expired PCO_2 , and again we exploit the fact that the PCO_2 of ideal gas and that of arterial blood are virtually the same. The physiologic dead space-to-tidal volume ratio is sensitive to tidal volume because of the large contribution of anatomic dead space. The normal value for physiologic dead space is less than 0.3. (For applications of these principles in pulmonary function testing, see Chapter 25.)

Distributions of Ventilation-Perfusion Ratios

The analysis of ventilation-perfusion inequality briefly described in the last section is sometimes known as the *three-compartment model* because the lung is conceptually divided into an unventilated compartment (shunt), an unperfused compartment (dead space), and a compartment that is normally ventilated and perfused (ideal). This way of looking at the diseased lung, which was introduced by Riley and Cournand,⁹² has proved to be of great clinical usefulness in assessing the effects of mismatching of ventilation and blood flow.

However, it was recognized many years ago that real lungs must contain some sort of distribution of ventilation-perfusion ratios and that a three-compartment model is therefore very remote from reality. The great difficulty of dealing with distributions of ventilation-perfusion ratios made progress very slow, although many clinical physiologists saw the measurement of distributions as an important goal.

The breakthrough came with the application of computer analysis of the behavior of distributions, a very complex area because of the nonlinear and interdependent oxygen and carbon dioxide dissociation curves. With computer analysis, it was possible to make considerable advances in the understanding of the behavior of distributions of ventilation-perfusion ratios.⁹⁵ This allowed the multiple inert gas elimination technique to become the standard research technique for measuring patterns of ventilation-perfusion distributions in normal subjects and patients with lung disease.⁹⁶

Multiple Inert Gas Elimination Technique. The principles governing inert gas elimination by the lung are identical to those of oxygen and carbon dioxide, and are dictated by equations corresponding to Equations 31 and 32. When an inert gas dissolved in saline is steadily infused into the peripheral venous circulation, it arrives at the lungs, and some of the gas will be exhaled. The proportion of gas that is eliminated by ventilation from the blood of a given lung unit depends only on the blood-gas partition coefficient of the gas (λ) and the ventilation-perfusion ratio (\dot{V}_A/\dot{Q}).^{100,101} The relationship is given by the following equation:

$$\frac{Pc'}{P\bar{v}} = \frac{\lambda}{(\lambda + \dot{V}_A/\dot{Q})} \quad [35]$$

where Pc' and $P\bar{v}$ are the partial pressures of the gas in end-capillary blood and mixed venous blood, respectively. Equation 35 looks different from Equations 31 and 32 only because inert gases obey Henry's law, allowing concentration to be replaced by the product of solubility and partial pressure. This in turn permits the rearrangement of terms ending up with Equation 35. The ratio of end-capillary to mixed venous partial pressure is known as the *retention*. This equation is derived from exactly the same considerations of mass balance as applied to carbon dioxide in Equation 5.

In practice, a mixture of six gases (typically, sulfur hexafluoride, ethane, cyclopropane, isoflurane, ether, and acetone) is dissolved in saline and infused into a peripheral arm vein at the rate of 3 mL/min until a steady state of gas exchange is achieved (10 to 20 minutes). Samples of mixed expired gas and arterial blood are then taken, and the gas concentrations in each are determined by gas chromatography. At the same time, cardiac output is obtained (e.g., by indicator dilution, echocardiography, or other method), and total ventilation is also measured. From these data, mixed venous concentrations of each inert gas can be calculated and retention determined. In patients who already have an indwelling pulmonary arterial catheter, a sample of mixed venous blood could be taken instead to measure mixed venous inert gas levels directly.

A graph is then constructed, as shown in Figure 4-24. The upper panel shows the data points of inert gas retention (arterial partial pressure divided by mixed venous partial pressure), which are joined for clarity by the broken line. Below this are the data points for excretion (mixed expired partial pressure divided by mixed venous partial pressure). Both are plotted against the partition coefficient. Again, the points are joined by a broken line. For comparison, the two solid lines show the values of retention and excretion for a lung with no ventilation-perfusion inequality but with the same overall ventilation and blood flow. The broken and solid lines are very close together in Figure 4-24, and the differences are more easily seen in Figure 4-25, where the lung is diseased.

These plots, called the retention-solubility and excretion-solubility curves, contain information about the distribution of ventilation-perfusion ratios in the lung. For example, if a lung contains units that are perfused but not ventilated (shunt), these particularly increase the retention of the least soluble gas, sulfur hexafluoride. Conversely, if the distribution contains large amounts of ventilation to lung units with very high ventilation-perfusion ratios, the excre-

Figure 4-24 Use of the multiple inert gas elimination technique to determine the distribution of ventilation-perfusion ratios in a 22-year-old normal subject. Upper panel, Data points for inert gas retention (upper curve) and excretion (lower curve). Broken lines join the points. The two solid lines show the values of retention and excretion for a lung with no ventilation-perfusion inequality. Lower panel, The recovered distribution of ventilation-perfusion ratios. SF_6 , sulfur hexafluoride. (Redrawn from Wagner PD, Laravuso RB, Uhl RR, West JB: Continuous distributions of ventilation-perfusion ratios in normal subjects breathing air and 100% O_2 . *J Clin Invest* 54:53–68, 1974.)

tion of the high-solubility gases is chiefly affected. The relationship between the distribution of ventilation-perfusion ratios and the retention-solubility and excretion-solubility curves can be expressed formally by a set of simultaneous linear equations.¹⁰² These equations, one for each inert gas, simply reflect the principles of mass conservation and relate the ventilation-perfusion distribution (i.e., the paired set of gas-exchange unit blood flows and ventilations) to a measured set of inert gas retention and excretion values. The distribution of ventilation-perfusion ratios that is consistent with the pattern of inert gas retention and excretion is then determined using computer programs that solve these simultaneous equations.

The potential and limitations of this transformation have been explored in great detail.¹⁰² The recovered distribution is not unique, but, in most cases, the range of possible distributions compatible with the data is small. No more than three modes of a distribution can be recovered, and only smooth distributions can be obtained. In spite of these limitations, however, the technique gives much more

Figure 4-25 Distribution of ventilation-perfusion ratios in a 60-year-old patient with COPD, predominantly emphysema. Upper panel, The retention and excretion solubility curves. Lower panel, The recovered distribution of ventilation-perfusion ratios. SF_6 , sulfur hexafluoride. (Redrawn from Wagner PD, Dantzker DR, Dueck R, et al: Ventilation-perfusion inequality in chronic obstructive pulmonary disease. *J Clin Invest* 59:203–216, 1977.)

information about patterns of distribution of ventilation-perfusion ratios in patients with lung disease than has previously been available.

Distribution in Normal Subjects. Figure 4-24 shows retention- and excretion-solubility curves and the derived distribution of ventilation-perfusion ratios from a 22-year-old normal volunteer.¹⁰³ First, note that the retentions and excretions as indicated by the data points and broken lines in the upper panel are almost superimposed on the solid lines for a homogeneous lung. The recovered distribution (lower panel) is consistent with these data and shows that the plots of both ventilation and blood flow are narrow, spanning only one decade of ventilation-perfusion ratios (i.e., from a ventilation-perfusion ratio of 0.3 to one 10 times higher, of 3). As expected, this range of ventilation-perfusion ratios is slightly greater than the regional differences, which mainly depend on gravity alone (see Fig. 4-22). However, there was essentially no ventilation or blood flow outside this range on the ventilation-perfusion ratio scale. Note also that there was no shunt, that is, blood flow to unventilated alveoli. The absence of shunt was a consistent finding in all the normal subjects studied and was initially surprising. It should be pointed out that, first,

this technique is very sensitive, in that a shunt of only 0.5% of the cardiac output approximately doubles the arterial concentration of sulfur hexafluoride. Apparently, young normal subjects are able to ventilate essentially all of their alveoli. Second, bronchial and thebesian shunts are not detected by the method.

In normal subjects the measured arterial PO_2 value is consistent with that modeled for a given ventilation-perfusion distribution and assuming diffusion equilibrium for oxygen. This means that ventilation-perfusion heterogeneity explains all of the difference between ideal alveolar PO_2 and arterial PO_2 in normal lungs. For example, in older normal subjects the dispersion of the ventilation-perfusion distribution increases, and this explains the gradual fall in arterial PO_2 observed with aging. Ventilation-perfusion mismatching must take place between lung units perfused by vessels 150 μm in diameter or larger to have a significant effect on arterial PO_2 .¹⁰⁴ This means the functional unit of oxygen exchange in terms of ventilation-perfusion matching is the acinus, or lung units distal to a terminal bronchiole.

Distributions in Lung Disease. Figure 4-25 shows a typical distribution of ventilation-perfusion ratios from a patient with COPD. The distribution is typical of the pattern seen in patients believed to have, predominantly, emphysema.¹⁰⁵ The upper panel shows that the measured retentions and excretions (dots, dashed lines) deviated greatly from those expected in a homogeneous lung with the same total ventilation and blood flow (solid lines). Consistent with this, the lower panel shows a broad bimodal distribution, with large amounts of ventilation to lung units with extremely high ventilation-perfusion ratios (alveolar dead space). Note the small shunt of 3.1%. The mild hypoxemia in this patient (arterial PO_2 of 63 mm Hg) is explained mostly by the slight displacement of the main mode of blood flow to the left of normal. Presumably the high ventilation-perfusion ratio mode reflects ventilation to lung units in which many capillaries have been destroyed by the emphysematous process, reducing their perfusion. Patients with acute pulmonary embolism often show a ventilation-perfusion ratio pattern similar to that in Figure 4-25. This is well explained by continuing ventilation in poorly perfused embolized regions. Sometimes shunts are seen as well, possibly from scattered atelectasis, possibly from edema, and possibly from right-to-left shunting through a patent foramen ovale when right atrial pressure is elevated.

Patients with COPD whose predominant lesion is severe bronchitis generally show a different pattern. The main abnormality in the distribution is a large amount of blood flow going to lung units with very low ventilation-perfusion ratios, between 0.005 and 0.1. This explains the more severe hypoxemia in this type of patient and is consistent with a large physiologic shunt. Presumably, the low ventilation-perfusion ratios in some lung units are the result of partially blocked airways due to retained secretions and airway disease that reduces airway diameter. However, it is interesting that these patients generally do not show much shunting (blood flow to unventilated alveoli), and a possible explanation is collateral ventilation. It should be emphasized that the distributions found in severe chronic bronchitis show considerable variability.

Figure 4-26 Distribution of ventilation-perfusion ratios in a patient with asthma before (A) and after (B) the administration of isoproterenol by aerosol. (Redrawn from Wagner PD, Dantzker D, Lacovoni VE, et al: Ventilation-perfusion inequality in asymptomatic asthma. *Am Rev Respir Dis* 118:511–524, 1978.)

A particularly interesting pattern of ventilation-perfusion ratios has been seen in some patients with asthma, even in remission.¹⁰⁶ Figure 4-26A shows an obvious bimodal appearance, with some 25% of the total blood flow going to lung units with ventilation-perfusion ratios in the region of 0.1. However, there was no blood flow to unventilated units. When this patient was given a β -adrenergic bronchodilator by aerosol, the distribution changed, as shown in Figure 4-26B. There was a marked increase in the amount of blood flow to low ventilation-perfusion ratio units, and this was associated with a corresponding decrease in arterial PO_2 from 81 to 70 mm Hg. However, the pattern was short lived; 5 minutes later, the distribution had returned to the pattern shown in Figure 4-26A, and the PO_2 was back to the prebronchodilator level. The bronchodilator effects of the drug on the airflow had a much longer duration.

Such a fall in arterial PO_2 is often seen in asthmatics after bronchodilator therapy even with improved airflow.^{60,61} The reason for the redistribution of blood flow is probably that the blood vessels supplying the hypoxic low ventilation-perfusion ratio units dilate preferentially in response to the β -adrenergic agonists. Modern bronchodilators cause less

hypoxemia than shown in Figure 4-26 and also less deterioration in the ventilation-perfusion ratio distribution.

It was surprising that this almost asymptomatic patient had as much ventilation-perfusion ratio inequality as shown in Figure 4-26. The extent of the abnormality of the distribution suggests that there were many more abnormalities in the lung, including obstruction of small airways, than were indicated by the patient's symptoms. One lung model consistent with the observed data is that half of the small airways may have been totally occluded by mucous plugs and/or airway wall edema, and that the lung subtended by them was ventilated through collateral channels. However, it should be emphasized that not all well-managed asthmatics show such abnormal distributions of ventilation-perfusion ratios. In some, the distribution is unimodal with little or no increase in dispersion. Importantly, the extent of ventilation-perfusion ratio inequality cannot be predicted from the impairment in spirometry.

Patients with acute respiratory distress syndrome commonly show a full spectrum of ventilation-perfusion ratio abnormalities, especially shunt, but also low ventilation-perfusion ratio regions, areas of normal ventilation-perfusion ratio, high ventilation-perfusion ratio regions, and increased ventilation of unperfused lung.

Newer techniques are being developed to image and quantify ventilation-perfusion matching, and even alveolar PO_2 , but they do not yet have the resolution of the multiple inert gas elimination technique.^{6,107} However, with sufficient spatial and temporal resolution, such methods could be useful for determining whether high ventilation-perfusion regions in patients with COPD (see Fig. 4-25) are indeed explained by the emphysematous bullae or whether the bimodal ventilation-perfusion distribution found in asthma (see Fig. 4-26) is regionally fixed or moves around.

Ventilation-Perfusion Inequality and Carbon Dioxide Retention

It is important to remember that ventilation-perfusion inequality interferes with the uptake and elimination of all gases by the lung (oxygen, carbon dioxide, carbon monoxide, and anesthetic gases). In other words, mismatching of ventilation and blood flow reduces the overall gas-exchange efficiency of the lung. There has been considerable confusion in this area, particularly about the role of ventilation-perfusion inequality in carbon dioxide retention.

Imagine a lung that is uniformly ventilated and perfused and that is transferring normal amounts of oxygen and carbon dioxide. Suppose that the matching of ventilation and blood flow is suddenly disturbed while everything else remains unchanged. What happens to gas exchange? It can be shown that the effect of this "pure" ventilation-perfusion inequality (i.e., with all other factors held constant) is to reduce both the oxygen uptake and carbon dioxide output of the lung.⁹⁵ The lung becomes less efficient as a gas exchanger for both gases, and therefore mismatching of ventilation and blood flow must cause hypoxemia and hypercapnia (carbon dioxide retention), other things being equal.

In practice, however, patients with ventilation-perfusion inequality often have a normal arterial PCO_2 . The reason for this is that, whenever the chemoreceptors sense a rising PCO_2 , there is an increase in ventilatory drive. The

consequent increase in ventilation to the alveoli usually returns the arterial PCO_2 to normal. However, such patients can only maintain a normal PCO_2 at the expense of this increased ventilation to their alveoli. The ventilation in excess of what they would normally require is sometimes referred to as *wasted ventilation* and is necessary because the lung units with abnormally high ventilation-perfusion ratios contribute little to eliminating carbon dioxide. Such units are part of the alveolar (physiologic) dead space.

Patients with ventilation-perfusion ratio inequality that causes carbon dioxide retention are sometimes said to be “hypoventilating,” but in fact they may actually be breathing more than normal. “Hypoventilation” as a synonym for hypercapnia is used by people who define the adequacy or inadequacy of alveolar ventilation by whether it maintains a normal arterial PCO_2 . “Alveolar ventilation” in this context does not refer to all the gas entering the lung alveoli but is related to “ideal alveolar” gas and excludes alveolar dead space gas. In this chapter the term *alveolar* has been used to refer to all the gas in the lung, excluding the conducting airways that contain anatomic dead space. True hypoventilation was discussed in an earlier section when the relationship between alveolar ventilation and PCO_2 was examined.

Historically it is easy to see how the term *hypoventilation* came to be applied so indiscriminately. When in the late 1950s it became possible to measure the PCO_2 of the arterial blood in the clinical setting, carbon dioxide retention was found to be a common and serious complication of chronic lung disease that could always be abolished by artificially increasing the ventilation. Thus it was natural to say that these patients had an abnormally low ventilation, and the term *hypoventilation* had the advantage of keeping an important therapeutic option in the forefront.

However, far from having a reduced ventilation, most of these patients are moving far more air into their alveoli than normal subjects. Indeed, all patients with chronic lung disease and ventilation-perfusion inequality who have a *normal* arterial PCO_2 must have *increased* the ventilation to their alveoli, and this applies to most patients with carbon dioxide retention as well.

Although patients with mismatched ventilation and blood flow can usually maintain a normal arterial PCO_2 by increasing the ventilation to the alveoli, this strategy is much less effective at increasing the arterial PO_2 . The reason for the different behavior of the two gases lies in the different shapes of the carbon dioxide and oxygen dissociation curves. The carbon dioxide dissociation curve is almost straight in the physiologic range, with the result that an increase in ventilation raises the carbon dioxide output of lung units with both high and low ventilation-perfusion ratios. By contrast, the nonlinearity of the oxygen dissociation curve means that not all lung units benefit from increased ventilation in terms of increasing oxygen concentration in their effluent blood. Those units with high ventilation-perfusion ratio, which operate high on the flat portion of the dissociation curve, increase the oxygen concentration in blood very little despite large increases in PO_2 . In units with a low ventilation-perfusion ratio, PO_2 in blood will increase more but, because such units operate on the steep portion of the dissociation curve, oxygen concentration remains close to that of mixed venous blood. The net

result is that the mixed arterial PO_2 rises only modestly, and some hypoxemia always remains.

In summary, carbon dioxide retention can result from two clearly distinct mechanisms: pure hypoventilation and ventilation-perfusion inequality. The latter is a common cause in clinical practice.

Effect of Changes in Cardiac Output on Gas Exchange in the Presence of Ventilation-Perfusion Inequality

In a lung with no ventilation-perfusion inequality, the cardiac output has no effect on arterial PO_2 or PCO_2 . This follows from Equations 5 and 17, which do not contain cardiac output. By contrast, these equations show that the level of total ventilation is very important.

However, in a lung with ventilation-perfusion inequality, cardiac output can have a major effect on arterial PO_2 , and this is important in some clinical settings. A reduction in cardiac output reduces the PO_2 of mixed venous blood, which in turn exaggerates the hypoxemia. This is sometimes seen in patients with myocardial infarction, in whom the reduction in arterial PO_2 seems to be out of proportion to the degree of ventilation-perfusion inequality. The opposite is sometimes seen in patients with bronchial asthma, who may have unusually high cardiac outputs, especially when treated with some β -agonist drugs. The result is that the arterial PO_2 is higher than would be expected from the degree of ventilation-perfusion inequality. This important modulating effect of cardiac output on gas exchange is often overlooked in the clinical setting.

OXYGEN SENSING

The responses of the body to hypoxia have been greatly clarified by the discovery of *hypoxia inducible factors* (HIFs). The initial finding was of a protein that bound to the hypoxia response element of the erythropoietin gene under hypoxic conditions.¹⁰⁸ Later it became clear that HIFs are critically important in a large number of responses of cells to hypoxia. In fact, it is now known that in cellular hypoxia the transcription of over a hundred messenger RNAs is increased and the expression of an equal number of messenger RNAs is decreased.¹⁰⁹

HIFs are transcription factors that are influenced by the amount of oxygen in the cell. A transcription factor is a protein that binds to specific DNA sequences in a gene and thus controls the flow of genetic information from DNA to messenger RNA. Cellular hypoxia causes an increased concentration of HIF-1 α which then binds to HIF-1 β and consequently influences the hypoxia response element. It is now known that most oxygen-breathing species express these transcriptional factors, indicating that HIFs have been highly conserved. For example HIF-1 is expressed in very primitive animals such as the worm *Caenorhabditis elegans* that do not have specialized respiratory or circulatory systems. This implies that HIF was initially developed to enhance the survival of individual cells in low-oxygen environments.

HIFs control genes that have many functions throughout the physiologic spectrum. These include mitochondrial genes involved with energy utilization, glycolytic enzyme genes influencing anaerobic metabolism, genes associated

with vascular endothelial growth factor controlling angiogenesis, genes of nitric oxide metabolism and ion channels on smooth muscle cells involved with the control of pulmonary blood flow, erythropoietin genes affecting red cell production, and genes controlling the induction of tyrosine hydroxylase, which plays a role in the function of the carotid body chemoreceptor.^{62a} Of particular interest is cancer, a condition that requires more energy¹¹⁰ that can be supplied by a HIF pathway. Furthermore, tumor-associated inflammation causes the induction of glycolytic pathways¹¹¹ that utilize HIF signaling. Thus HIFs constitute a master switch in the general response of the body to hypoxia.

Key Points

- The magnitudes of ventilation and perfusion, as well as their distribution, are key factors determining pulmonary gas exchange.
- Distribution of ventilation and perfusion is predominantly affected by gravity in the normal lung, but intrinsic lung structure also plays a role.
- Distribution of ventilation-perfusion (\dot{V}_A/\dot{Q}) ratios is nonuniform, the \dot{V}_A/\dot{Q} ratio being generally higher in nondependent lung regions and lower in dependent lung regions.
- Regional alveolar P_{O_2} and P_{CO_2} are determined principally by the \dot{V}_A/\dot{Q} ratio of each region. Secondary factors are the P_{O_2} and P_{CO_2} of inspired gas and mixed venous blood and also the shape of the oxygen and carbon dioxide dissociation curves.
- There are four causes of hypoxemia: hypoventilation, alveolar-capillary diffusion limitation, shunt, and \dot{V}_A/\dot{Q} inequality.
- There are two principal causes of hypercapnia: hypoventilation and \dot{V}_A/\dot{Q} inequality.
- \dot{V}_A/\dot{Q} inequality is the most important cause of gas-exchange abnormalities in most lung diseases.

INTRODUCTION

The movement of gases in and out of the respiratory system may be described by the physical laws that govern pressure, volume, and flow of gas. The study of these relationships is called “respiratory mechanics,” and the study of the energy cost of gas movement is called “energetics.”

This chapter reviews basic terminology, respiratory mechanics under static and dynamic conditions, and energetics, including measurements of the work of breathing. The chapter also highlights how physiologic principles can be applied to specific clinical problems.

TERMINOLOGY

FLOW

Flow is defined as the volume of gas passing a fixed point per unit of time. Flow is usually measured with a pneumotachygraph (flowmeter), which consists of a tube with a known fixed resistance. Flow can be calculated by measuring the pressure drop across the resistor.

Gas velocity is the distance moved by a gas molecule per unit of time and should not be confused with flow. At a constant flow, gas velocity will be greater in narrower tubes (Fig. 5-1).

VOLUME

Volume is defined by the space occupied by a gas. The volume occupied by a fixed number of gas molecules is determined by temperature and pressure.

The volume of gas entering and leaving the lung can be determined by a spirometer that measures volume displacement or by integrating the flow signal measured by a pneumotachygraph. The subdivisions of lung volumes are shown in Figure 5-2. Some of these subdivisions can be measured

by spirometry alone (vital capacity, tidal volume), whereas others require use of plethysmography or helium dilution. *Total lung capacity* (TLC) is the lung volume at the end of a maximal inspiration. Residual volume is the volume at the end of a maximal expiratory effort. *Functional residual capacity* (FRC) refers to the volume in the lung at the end of a normal tidal exhalation, when there is normally relaxation of both inspiratory and expiratory muscles.

Total gas volume in the lung is usually measured at FRC using plethysmographic methods or by inert gas dilution methods, and each of these techniques has advantages and disadvantages.¹ Traditional body plethysmography is widely available and accurate. For the body plethysmography technique, subjects are completely enclosed in a gas-tight container. Lung volume can be calculated by comparing changes in alveolar pressure (measured at the mouth while the patient pants against an occluded mouthpiece) with changes in pressure in the container.² Body plethysmography may overestimate lung volumes because it will include measurement of abdominal gas if that gas is compressed and decompressed during the panting maneuver. Plethysmographs that use electrical inductance^{3,4} or optical data⁵ have been advanced as noninvasive methods for the measurement of lung volumes in those not able to tolerate traditional plethysmography. However, given the limited experience with these modalities in clinical settings, they are best considered experimental advances at this time.^{6,7}

Because spirometry cannot estimate FRC, one of several inert gas dilution techniques (usually with helium or nitrogen) or radiologic assessments is used. Historically, inert gas methods have usually used helium. For this method, subjects at FRC inhale a known concentration and volume of helium. The helium mixes with and is diluted by the gas already in the lung. A sample of exhaled gas is analyzed for helium concentration, allowing calculation of the FRC thus:

$$C_1 \times V_1 = C_2 \times (V_1 + \text{FRC})$$

Figure 5-1 Laminar flow through a tube. A, Schematic depiction of the spatial and velocity profiles of gas molecules within a laminar flow system. The velocity of the gas molecules is proportional to the length of the arrows. For laminar flow, velocity is greatest in the center of the tube and least close to the edge. B, When tube diameter is reduced, the same gas flow rate will result in increased velocity of the individual gas molecules. C, During laminar flow, there is a linear relationship between pressure and flow.

Figure 5-2 Subdivisions of lung volume. Volume-time tracing of a subject taking two normal tidal breaths, inhaling to total lung capacity (TLC), and exhaling to residual volume (RV). Vital capacity (VC) and inspiratory capacity (IC) may be measured with a spirometer. The measurement of functional residual capacity (FRC), RV, and TLC requires a determination of intrathoracic gas volume by plethysmography, helium dilution, or nitrogen washout.

where C_1 is the initial (known) helium concentration in the bag, C_2 is the final (measured) helium concentration, and V_1 is the initial volume of gas in the bag. Therefore

$$FRC = V_1 \times (C_1 - C_2) / C_2$$

By the same principle other nonrespiratory gases, such as sulfur hexafluoride (SF_6), may be used to calculate FRC. In general, inert gas dilution measurements tend to underestimate total lung volume, especially in patients with substantial airway obstruction who may have gas trapped in lung units that does not mix with inspired gas.

Another method uses the respiratory gases naturally present in a subject's lungs (such as nitrogen) to be used for FRC determination. In the simplest form, measurement of FRC using the nitrogen dilution method requires the subject to be ventilated with a 100% oxygen gas mixture to allow the washout of nitrogen from the respiratory system. Once all the nitrogen has been washed out, the initial gas mixture (oxygen/air) is reinstituted, and the concentration of nitrogen is repeatedly sampled until it returns to the baseline level. The trajectory of nitrogen concentration in the exhaled gas allows the estimation of FRC. Unfortunately, the basic technique is complicated by time delays from gas analyzers. Adjustment for these delays is possible but is complex because the delay depends on gas viscosity, which changes as the nitrogen and oxygen concentrations change.⁸

Figure 5-3 Respiratory system pressures. Pao, pressure at airway opening; Pbs, pressure at body surface; Palv, pressure in alveolus; Ppl, pressure in pleural space; Pab, pressure in abdomen. Transpulmonary pressure: $P_{ao} - P_{pl}$; translung pressure: $P_{alv} - P_{pl}$; transchest wall pressure: $P_{pl} - P_{bs}$; transrespiratory system pressure: $P_{ao} - P_{bs}$; transdiaphragmatic pressure: $P_{pl} - P_{ab}$. Under static conditions, when the subject is not on assisted ventilation, Pao is equal to 0 (atmospheric pressure). However, Pao may be positive when the patient is receiving positive-pressure mechanical ventilation. Pbs is equivalent to atmospheric pressure unless the subject is in a negative pressure device such as an iron lung.

Imaging modalities such as computed tomography (CT) and magnetic resonance imaging can provide accurate assessment of FRC.^{6,9-12} CT may overestimate the volume of alveolar gas available for gas exchange because it measures the entire volume of gas in the lung irrespective of whether that gas is trapped and is not partaking in gas exchange.⁸

PRESSURE

The pressure of a gas is generated from the momentum of molecules colliding against a surface and is expressed as the force per unit area. Pressure, as opposed to force, is the same in all directions. Respiratory system pressures are usually reported relative to atmospheric pressure.

The pressures relevant to the respiratory system are shown in Figure 5-3. Although it is possible to measure pleural pressure directly, it is usual to use esophageal pressure as a less invasive surrogate. Esophageal pressure may be measured using an air-filled balloon inserted into the middle third of the esophagus, approximately 35 to 45 cm from the nares.¹³⁻¹⁵ Balloons placed in the proximal third can be affected by movement of the neck, and balloons placed in the distal third can record falsely high readings owing to compression by the heart. Absolute values of pressure may be difficult to interpret in the supine position owing to the weight of the mediastinum.

THE COMBINED GAS LAW

For an ideal gas the relationship between volume, pressure, temperature, and the number of molecules of gas is described by the combined gas law:

$$PV = nRT$$

where P is the absolute pressure of the gas, V is the volume, n is the number of moles of gas, R is the universal gas

Figure 5-4 Balloon-and-tube analogy of the respiratory system, where ΔP_{TM} = change in transmural pressure (inside – outside) of the balloon; ΔV = change in volume; C = compliance; \dot{V} = flow; R = resistance; and ΔP_{tube} = pressure difference from one end of the tube to the other.

constant (8.3145 J/[mol K]), and T is the temperature in degrees Kelvin.

This equation summarizes earlier gas laws, including Boyle's law ($PV = \text{constant}$), Charles' law ($V/T = \text{constant}$), Gay-Lussac's law ($P/T = \text{constant}$), and Avogadro's law ($n/V = \text{constant}$). The volume of a gas should thus increase as the number of molecules of gas increases, the temperature increases, or the applied pressure decreases. Although this equation theoretically applies only to an ideal or perfect gas, it is an adequate approximation for clinical purposes.

COMPLIANCE, RESISTANCE, AND TIME CONSTANTS

The respiratory system can be thought of as a combination of balloons and tubes (Fig. 5-4). As the pressure across the wall of a balloon increases (called “transmural pressure,” or “pressure inside minus pressure outside”), the volume inside the balloon increases (see Fig. 5-4). The ratio between the change in volume and the change in transmural pressure is the compliance of the balloon. The units of compliance are volume/pressure. A large compliance indicates that volume changes markedly for every change in pressure. The inverse of compliance is elastance, with a greater value indicating a stiffer system.

Resistance is a measure of the pressure required to generate flow through a tube. The narrower the tube, the greater the pressure needed and the higher the resistance. The units of resistance are pressure/flow. The inverse of resistance is conductance, with a greater value indicating a more dilated airway. Flow in a tube may be laminar or turbulent, with significant implications for the amount of pressure drop or energy required to drive gas movement.

When a pressure is applied to a lung unit (Fig. 5-5), the time required to fill the unit is dependent on its compliance and resistance. That is, it will take longer to fill if resistance is high because the flow will be reduced. Similarly, it will take longer to fill the unit if compliance is high because it will require more volume. The product of the *resistance and compliance* (RC) of a lung unit is the time constant and represents the time required for the lung unit to fill to 63% of the final volume if a constant pressure is applied. Areas of the lung with small time constants (i.e., low resistance and/or low compliance) will fill more rapidly than areas with larger time constants.

Figure 5-5 Time constants. Shown are two units of equal volume, one with a very short time constant, A, and one with a long time constant, B. Each is inflated under a constant pressure until point **, and then exhalation is passive. At point **, unit A is completely filled, but unit B is not. Of note, when time constants are uneven as shown here, decreasing inspiration time to point * will worsen heterogeneity in ventilation.

The effect of variations in time constants of lung units is shown in Figure 5-5. This concept has clinical implications when there are heterogeneous time constants between parallel lung units, as in patients with chronic airflow obstruction or with patchy alveolar edema/atelectasis as is found in *acute respiratory distress syndrome* (ARDS). As long as respiratory frequency is slow, all units will fill to their static equilibrium. However, if respiratory rate increases so that the inspiratory time becomes less than the time constant of some units, these units will receive less ventilation and contribute to ventilation-perfusion mismatch.

RESPIRATORY MECHANICS IN STATIC CONDITIONS

We first consider the lung during static conditions, during which measurements are made while the respiratory system is maintained at a fixed volume with no gas flow. Even under static or no-flow conditions, pressure gradients are still required to distend the respiratory system (analogous to the balloon described previously). The energy used to distend the respiratory system during inhalation (elastic work) is stored as potential energy. Because of this stored energy, normal exhalation does not require work and is a passive process. This contrasts with resistive work (discussed later in this chapter), which cannot be stored as potential energy and is dissipated as heat. The elastic work performed to inflate the respiratory system has both lung and chest wall components.

ELASTIC RECOIL OF THE LUNGS

If removed from the body, an isolated lung will deflate because of its elastic recoil to a minimal volume containing only trapped gas. Because airways close before complete alveolar emptying, application of a negative pressure to the airway opening will not remove the trapped gas. The relationship between lung volume and transpulmonary pressure during inflation is shown in Figure 5-6. Lung compliance is fairly high at the lung volumes associated with normal breathing but then decreases markedly near TLC. At TLC, very large increases in transmural pressure result in small changes in volume.

Figure 5-6 Volume-pressure curves of lung and chest wall. The relationship between transmural (inside – outside) pressure of lung and relaxed chest wall volume are shown. The static equilibrium of the chest wall is above FRC, whereas that for the lung is below FRC (arrows).

Two major factors are responsible for the elastic recoil of the lung: (1) lung connective tissue and (2) surface tension related to the air-liquid interface of the alveolar surface.

Lung Connective Tissue

A network of connective tissue fibers provides the framework for the alveoli and structural integrity for the lung. The fibers are composed mostly of collagen and elastin. Collagen fibers exhibit high tensile strength but are relatively noncompliant. They can be extended by only 2% of their length.¹⁶ This contrasts with elastin, which has a lower tensile strength and is more compliant; elastin fibers can be stretched by as much as 130% of their length. Experiments using selective destruction of fibers by collagenase or elastase show that elastin fibers are the major contributors to the volume-pressure relationships at low lung volumes, whereas collagen is more important at higher volumes approaching TLC.^{17,18} At low lung volumes, elastin fibers bear much of the stress, and collagen fibers are curled and unstressed. As lung volume increases, collagen fibers uncurl and straighten and have a major stiffening effect on the lung. In other words, the major role of collagen is to limit overdistention of the lung, and the major role of elastin is to facilitate inflation while providing lung stability to maintain the configuration of internal structures.

Destruction of lung connective tissue, from smoking-induced emphysema for instance, can substantially increase lung compliance.¹⁹ Contraction of smooth muscle in the airways and alveolar ducts may also affect elastic recoil because contraction of smooth muscle reduces volume by exerting traction on the lung (similar to a drawstring).²⁰ Although contraction of airway smooth muscle in the peripheral lung units (small airways and alveolar ducts) changes lung compliance in several different animal species, there is little effect of contraction of lung smooth muscle on the shape of the volume-pressure curve in humans.²¹⁻²³

Alveolar Surface Forces and Surfactant

When a lung is completely filled with water, compliance is much greater than when it is filled with air.²⁴ This suggests that the majority of lung elastic recoil is due to surface tension at the air-liquid interface lining the alveoli, rather than the recoil from elastin and collagen connective tissue fibers (see Chapter 8 for more details).

Because there are intermolecular forces of attraction between molecules of liquids, the surface of an air-liquid

Figure 5-7 Laplace's law. Consider two gas-filled fluid bubbles with equal surface tension (T) but differing radii (R and r), connected by a tube. Because of the smaller radius of curvature, the pressure in the smaller bubble will exceed that of the larger ($P_2 > P_1$), leading to gas flow from the smaller to the larger bubble.

interface is under tension. That is, a molecule in the interior of a liquid is subjected to an equal force in all directions by other liquid molecules. However, the molecules at the surface are pulled toward each other and by molecules below the surface, and these forces (surface tension) cause a tendency for the surface to collapse.

Because of surface tension, a positive pressure must be present to prevent the collapse of a gas-filled bubble in a liquid. The pressure of gas (P) within a bubble is related to the surface tension (T) and the radius of curvature of the bubble (r) by Laplace's law ($P = 2T/r$) (Fig. 5-7). The surface of the alveolus with an air-liquid interface can be likened to a bubble with a radius of approximately 0.1 mm at FRC. If the surface tension were similar to that of water (72 mN/m), the lungs would be very noncompliant and ventilation with transpulmonary pressures in the physiologic range (3 to 5 cm H₂O) would be impossible. Furthermore, the high surface tension would lead to alveolar instability and cause alveolar collapse. That is, smaller alveoli with smaller radii of curvature, by the nature of Laplace's law, would have higher alveolar pressures than larger alveoli with greater radii of curvature. Because gas travels from an area of higher pressure to one of lower pressure, smaller alveoli would tend to empty into larger alveoli, eventually resulting in one large air-filled alveolus with all other alveolar units collapsed.

A number of factors contribute to alveolar stability in normal lungs. First, the connective tissue scaffolding limits overdistention of alveoli. Second, alveoli are interconnected (alveolar interdependence) by common walls and structures. Therefore, if one alveolus began to collapse, it would stretch adjacent alveolar walls, creating a tethering effect on the collapsing unit. Third, surfactant has an important stabilizing effect.

Hysteresis and Stress Adaptation

When normal lungs are inflated and deflated slowly, the volume-pressure curves are not identical. During inflation of the lung, the pressure required at any given lung volume is greater than that during deflation (Fig. 5-8). The difference between the inflation and the deflation curves is due to hysteresis and stress adaptation.

Hysteresis refers to changes in mechanical properties due to the volume history of the lung and is caused by several

factors. First, the effect of surfactant on surface tension is dependent on volume history, with surfactant less effective at reducing surface tension during inspiration than during expiration. During inspiration the phospholipids of surfactant move to the surface of the liquid layer, and during exhalation the surface film is compressed, the phospholipids are concentrated, and surface tension falls. Second, much higher pressures are required to open collapsed airways or alveoli than are required to keep them open. In disease states characterized by collapse of alveoli (e.g., ARDS), significant hysteresis of the pressure volume curve can be seen²⁵ (see Fig. 5-8). This has clinical significance in patients with ARDS because higher inflation pressures are required to ventilate the lungs.

In contrast, stress adaptation refers to the time dependence of mechanics measurements. When lung tissue is stretched to a particular length, the tension required to maintain the length gradually diminishes due to time-dependent properties of surfactant and deformation of viscoelastic tissues of the lung. Therefore, after a sustained lung inflation, the pressure required to keep the lung at that volume will decrease.

Figure 5-8 Hysteresis in a normal lung (A) and in an acutely injured lung (B). In acute respiratory distress syndrome (ARDS), the lung is stiffer than the normal lung, and greater inflation pressure is required at any given lung volume. Furthermore, the degree of hysteresis is much greater in ARDS lungs, with a greater separation of the volume-pressure curves on inspiration (upward arrow) and exhalation (downward arrow). FRC, functional residual capacity.

Recruitment Maneuvers in Acute Respiratory Distress Syndrome

ARDS is a disease known to have surfactant dysfunction. The dysfunction of surfactant increases surface tension at the air-liquid interface of the alveoli, leading to collapse, intrapulmonary shunting, and hypoxemia.²⁶ Because of alveolar collapse, hysteresis may be especially apparent in patients with ARDS (see Fig. 5-8). The lung collapse necessitates high inflation pressures to ventilate the lungs, thereby increasing the work of breathing and potentially leading to barotrauma; low tidal volumes are used in ARDS to mitigate further lung injury.²⁷

Due to hysteresis the pressure required to open an alveolus (“opening pressure”) is significantly greater than the pressure at which an already open alveolus will collapse (“closing pressure”). Because of this, “recruitment maneuvers” have been used in ventilated patients with ARDS who remain hypoxemic despite moderate levels of externally applied *positive end-expiratory pressure* (PEEP).²⁸⁻³² A recruitment maneuver consists of a sustained inflation at a constant high pressure, which opens collapsed alveoli. Because closing pressures are much less than opening pressures, the alveoli stay open (at least temporarily) after the sustained inflation is ended, as long as the lung is not allowed to return to a very low volume (Fig. 5-9).

ELASTIC RECOIL OF THE CHEST WALL

The chest wall is made up of the rib cage laterally, the sternum anteriorly, the vertebral column posteriorly, and the diaphragm caudally. Movement of the chest wall by the muscles of ventilation generates pressure gradients between the alveoli and the surrounding air, enabling gas to be moved in and out of the lungs.

Respiratory Muscles (see Chapter 97)

The diaphragm consists of two separate muscles joined by a central tendon. The crural diaphragm arises from the first three lumbar vertebrae and the medial and lateral arcuate ligaments. The costal diaphragm arises from the inner surfaces and upper margins of the lower six ribs and sternum. Both costal and crural fibers insert onto the central tendon. The phrenic nerve innervates the diaphragm, with costal fibers innervated from the 3rd and 4th cervical spinal segments, and crural fibers from the 4th and 5th segments. In

Figure 5-9 Recruitment in acute respiratory distress syndrome (ARDS). CT scan of the lung in a patient with ARDS at 5 cm H₂O airway pressure (left) and at 45 cm H₂O pressure (right), demonstrating lung recruitment with higher airway pressures. (From Gattinoni L, Caironi P, Cressoni M, et al: Lung recruitment in patients with the acute respiratory distress syndrome. *N Engl J Med* 354:1775–1786, 2006, with permission.)

Figure 5-10 Normal subject and patient with chronic obstructive pulmonary disease (COPD). A, In a normal subject the lower part of the diaphragm lies next to the lower rib cage (zone of apposition). As indicated by the arrows, contraction of the diaphragm will pull the dome downward and push the lower rib cage upward and outward (due to increased abdominal pressure). B, In a patient with COPD and hyperinflation, there is loss of the zone of apposition. As indicated by the arrow, contraction of the diaphragm may lead to inward movement of the lower rib cage.

normal subjects the lower part of the rib cage encloses the upper part of the abdomen at FRC. In this area the diaphragm is pushed against the lower rib cage (zone of apposition) with fibers arranged in a cranial-caudal direction (Fig. 5-10). Contraction of the diaphragm leads to a piston-like up-and-down motion of the diaphragm. Furthermore, diaphragm contraction leads to an increase in abdominal pressure, which pushes the rib cage upward and outward.^{33,34}

In patients with substantial hyperinflation (e.g., emphysema), the position of the diaphragm is lower, with loss of the zone of apposition.³⁵ When the zone of apposition is lost, contraction of the diaphragm is less mechanically advantageous and can result in paradoxical inward movement of the lower rib cage during inhalation (the Hoover sign) and less piston-like motion of the diaphragm dome.³⁶ Furthermore, the length of the diaphragm is shortened, which creates a further mechanical disadvantage because the ability of the muscle to generate force is attenuated at shorter lengths (Fig. 5-11). However, in animals and humans, compensatory shortening of the diaphragm through loss of sarcomeres has been shown to mitigate these effects and help to improve the length-tension characteristics of the diaphragm.^{37,38} The improved symptoms experienced by patients with *chronic obstructive pulmonary disease* (COPD) following lung volume reduction surgery or after removal of pleural effusions may be related to increased length of the zone of apposition and improved mechanical function of the diaphragm.³⁹

Figure 5-11 Force-length characteristics of skeletal muscle. Skeletal muscle displays a characteristic force-length curve with a reduction in force-generating capacity at lengths below or above optimal length (Lo).

Figure 5-12 Movement of rib cage during inspiration. Diagram indicating pump-handle (A) and bucket-handle (B) rotations of the ribs. In both panels the sternum and rib are shown before (gray) and after (purple) rib cage expansion. (From De Troyer A, Loring SH: Actions of the respiratory muscles. In Roussos C, editor: *The thorax*, part A. New York, 1995, Marcel Dekker, pp 535–563.)

During inhalation the rib cage moves laterally and anteriorly. The anterior motion of the sternum is akin to a “pump-handle,” motion, and the lateral movement and elevation of the ribs is akin to a “bucket-handle” motion (Fig. 5-12). The muscles of the rib cage include the internal intercostal muscles, the external intercostal muscles, and the parasternal muscles. Internal intercostal muscles are used mainly for exhalation, whereas external muscles are used for inhalation.⁴⁰ The parasternal muscles are located next to the sternum; although they are part of the internal intercostal muscle layer, their major function is to raise the sternum during inhalation.⁴¹

Other muscles used in inhalation include the scalene muscles, which help to elevate the rib cage and prevent paradoxical inward movement of the upper rib cage with diaphragm displacement.⁴² Under conditions of ventilatory stress, other muscles not normally used for respiration can be recruited. These include the sternocleidomastoid, pectoralis, trapezius, and muscles of the vertebral column. Contraction of the muscles in the abdominal wall can be used to aid exhalation.

Fatigue of Respiratory Muscles

Fatigue develops when the rate of work required by the muscles exceeds the rate of energy supply. Usually there is substantial reserve of the respiratory muscles that prevents fatigue. However, under conditions of excessive elastic or resistive load (either experimentally induced or due to disease states) and/or inadequate energy supply (e.g., during hypoxemia or cardiogenic shock), fatigue develops

and impairs respiratory muscle performance.⁴³⁻⁴⁵ Recovery from fatigue usually requires more than 24 hours of rest.⁴⁶

One measure of workload of the diaphragm is the pressure-time index. This is the product of the percentage of maximal pressure (i.e., transdiaphragmatic pressure/maximal transdiaphragmatic pressure) exerted by the muscle multiplied by the percentage of time spent during inspiration (inspiratory time/total time). In normal subjects a value greater than 15% to 18%, if sustained, will lead to fatigue and loss of force-generating capacity of the diaphragm.⁴⁷

Central respiratory fatigue arises when there is a reduction in central motor output to the muscles. Central fatigue can be identified when direct electrical stimulation of respiratory muscles produces more muscle force generation than the patient generates with a maximal voluntary effort.⁴⁸ This decrease in central motor output may represent an attempt to prevent damage to the muscles under conditions of inadequate energy supply. Peripheral fatigue represents failure at or past the level of the neuromuscular junction. With peripheral fatigue, force generation is reduced despite a constant electrical stimulation. Peripheral fatigue may arise because of failure of transmission at the neuromuscular junction, reduced adenosine triphosphate level, reduced calcium availability from the sarcoplasmic reticulum, or reduced calcium sensitivity of the myofilaments (caused by acidosis or increased inorganic phosphate).⁴⁹

Respiratory Muscle Atrophy during Positive-Pressure Mechanical Ventilation

Although excessive loading of the respiratory muscles can lead to fatigue and a reduction in force generation, excessive unloading of the muscle may lead to muscle atrophy. Mechanical ventilation in paralyzed rats and baboons leads to diaphragmatic atrophy.^{50,51} Furthermore, human studies in organ donors have shown significant diaphragmatic atrophy after 18 to 69 hours of diaphragmatic inactivity.⁵² However, the clinical significance of disuse atrophy in ventilated patients is still unclear. Patients who are not paralyzed may still have substantial activation of respiratory muscles while receiving mechanical ventilation,^{53,54} and this degree of stimulation may be adequate to prevent atrophy.⁵⁵⁻⁵⁷ Furthermore, there are other potential causes of muscle weakness or injury in the intensive care unit, including electrolyte disturbances, malnutrition, medications and toxins (e.g., alcohol, corticosteroids, aminoglycosides), sepsis-related cytokines, and inflammatory disorders (e.g., polymyositis), so that attributing muscle weakness to disuse atrophy of muscle fibers in the clinical setting is difficult.

Chest Wall Compliance (see Chapter 98)

The compliance of the chest wall can be determined by measuring changes in the transmural pressure across the thorax (pleural pressure minus body surface pressure) relative to change in volume. The volume-pressure curve of the relaxed chest wall is shown in Figure 5-6. In contrast to the lung, the resting volume of the relaxed chest wall is approximately 1 L above FRC. The difference between the resting volume of the lung and chest wall can be appreciated in patients with a pneumothorax, in which the chest wall recoils outward and the lung recoils inward. When the

chest wall is distended above this resting volume, the relaxed chest wall recoils inward, and when the chest wall is moved below this resting volume, it recoils outward. The compliance of the normal chest wall is approximately 200 mL/cm H₂O, but it becomes progressively stiffer at lower lung volumes, and it is this stiffness that predominantly determines residual volume in normal young subjects.⁵⁸

Factors such as ossification of costal cartilage, arthritis of costovertebral joints, skin eschars from burns, obesity, and abdominal distention may reduce chest wall compliance. Chest wall compliance increases in the sitting position compared with the supine position, but the overall effect is usually modest.⁵⁹

INTEGRATION OF LUNG AND CHEST WALL MECHANICS

The chest wall and lung are juxtaposed and, in the absence of pleural disease (such as pneumothorax or pleural fibrosis), changes in chest wall volume are essentially identical to changes in lung volume (Fig. 5-13). An integration of lung and chest wall mechanics can be graphically represented by plotting the pleural pressure against the relaxed volumes of the lung and chest wall (Campbell diagram) (Fig. 5-14). These plots help to explain the determinants of the commonly measured static lung volumes. At FRC (relaxation volume), the outward recoil pressure of the chest wall is balanced by the inward recoil of the lung. The pleural pressure at FRC is negative (approximately -3 to -4 cm H₂O) in normal subjects. Changes in the compliance of the lung or chest wall may change the relaxation volume (see Fig. 5-14).

Increases in lung compliance (e.g., due to emphysema) will tend to shift the volume-pressure curve of the lung upward and to the left. If chest wall compliance remains constant, FRC will increase. In contrast, if lung compliance is reduced (e.g., due to pulmonary fibrosis or ARDS), the

Figure 5-13 Changes in pleural pressure with applied positive end-expiratory pressure (PEEP). A, A lung is shown at end-expiration with no PEEP. B, With the application of PEEP, there is an increase in the volume of the respiratory system (lung and chest wall) and an increase in pleural pressure (Ppl). The magnitude of the increase in Ppl is dependent on the relative compliances of the lung and chest wall. Palv, pressure in alveolus.

Figure 5-14 Integration of lung and chest wall mechanics. Changes in lung and relaxed chest wall volumes as a function of pleural pressure (Campbell diagram). This is basically the same plot as in Fig. 5-6 except that the x-axis is simply pleural pressure rather than transmural pressure for the lung and chest wall. The point at which the two curves meet is the functional residual capacity (FRC) (lung recoil balanced by chest wall recoil). If lung compliance is increased (e.g., in chronic obstructive pulmonary disease [COPD]), the point at which the two curves meet (FRC) is greater (point A). In contrast, if lung compliance is reduced (e.g., in pulmonary fibrosis), the point at which the two curves meet is less (point B).

Figure 5-15 Maximal inspiratory effort (Campbell diagram). With maximal inspiratory effort the volume-pressure curve of the chest wall moves to the right. The point at which there is intersection of this curve and the lung volume-pressure curve is the total lung capacity (TLC). FRC, functional residual capacity.

volume-pressure curve of the lung will shift downward and to the right, leading to a reduction in FRC. Similarly, changes in chest wall compliance can lead to increases or decreases in FRC.

FRC is believed to represent the balance of forces in a relaxed state at which there is no muscle activation. However, FRC may not be completely passively determined. There is a reduction in FRC with paralysis compared with the relaxed state, suggesting that inspiratory muscle tone of the rib cage muscles and diaphragm may contribute to “passive” chest wall compliance and thus to FRC.⁶⁰

With activation of inspiratory and expiratory muscles, the configuration of the chest wall changes. This is demonstrated in Figure 5-15. Activation of inspiratory muscles effectively shifts the pressure-volume curve of the chest wall, so that at any given pleural pressure, the chest wall volume is increased relative to the relaxed state. The horizontal difference between the relaxed curve and the curve with inspiratory muscle activation represents the net pressure generated by the inspiratory muscles.

TLC is determined by the balance between the strength of the inspiratory muscles counterbalanced by the inward lung recoil plus the inward chest wall recoil. However, in normal subjects, TLC is predominantly determined by the markedly increased stiffness of the lung at high lung volume, rather than the recoil of the chest wall or respiratory muscle strength.⁶¹ In support of this concept, inspiratory muscle training in normal subjects increases strength substantially (55% increase in maximal inspiratory pressure) but results in a very modest change in TLC and VC (about 4%).⁶² The situation in patients with neuromuscular disease is very different; in such individuals, reduced TLC is largely due to respiratory muscle weakness and can be improved to some extent by inspiratory muscle training.⁶³

Activation of expiratory muscles shifts the pressure-volume curve of the chest wall in the other direction, and the degree of shift is a measure of the net pressure exerted by the expiratory muscles. In young subjects, residual volume is determined by the balance of the strength of the expiratory muscles counterbalanced by the outward recoil of the chest wall and inward lung recoil (small component).⁶¹

In older subjects or patients with obstructive lung disease, residual volume is not determined by this balance of forces but is rather determined by airway closure. In such individuals, airways close and gas is trapped during exhalation before a static balance is achieved.⁶¹

Calculation of Total Respiratory System Compliance from Lung and Chest Wall Compliance

The chest wall and lung act as capacitors in series, analogous to electrical capacitors. The relationship between total respiratory system compliance and lung and chest wall compliance is indicated by the following formula:

$$1/\text{Total compliance} = 1/\text{Lung compliance} + 1/\text{Chest wall compliance}$$

Alternatively, since elastance = 1/compliance,

$$\text{Total elastance} = \text{Elastance of lung} + \text{Elastance of chest wall}$$

As an example, in a supine paralyzed subject, lung compliance is approximately 150 mL/cm H₂O pressure, and chest wall compliance is approximately 200 mL/cm H₂O pressure⁶⁴; the calculated compliance of the respiratory system would thus be approximately:

$$1/(1/200 + 1/150) = 85.7 \text{ mL/cm H}_2\text{O}$$

CLINICAL APPLICATIONS

The Impact of Positive End-Expiratory Pressure on Pleural Pressure

In patients receiving positive-pressure mechanical ventilation for diseases that decrease lung compliance, pressure is usually applied at the end of exhalation to prevent alveolar collapse.⁶⁵ Some—but not all—of this PEEP is transmitted from the alveolar space to the pleural space (see Fig. 5-13). This is important because pericardial pressure will increase

to a similar extent as pleural pressure. An increase in pericardial pressure reduces venous return and can lead to reduced cardiac output and hypotension.⁶⁶ Furthermore, PEEP will increase central venous pressure and pulmonary artery occlusion pressure to a magnitude similar to the increase in pleural pressure. If this is not taken into account, errors may be made when using these pressures to assess patients' intravascular volume status.

During mechanical ventilation, changes in both pleural pressure and transpulmonary pressure depend on the relationships between the elastance of the chest wall (E_w), the lung (E_L), and the total respiratory system (E_{rs} , which is the sum of E_w and E_L), a relationship (see Fig. 5-13) that may be described by the equation:

$$P_{pl} = PAW \times E_w / E_{rs}$$

where P_{pl} is the pleural pressure and PAW is the flow-resistive pressure in the airway.

In healthy individuals, E_w and E_L are approximately equal, and E_w/E_{rs} has a value of approximately 0.5⁶⁷ and remains constant within the range of normal ventilation. In this situation it is reasonable to infer the value of P_{pl} from PAW . However, in disease, both E_w and E_L demonstrate great variability, such that the ratio of E_w to E_{rs} is unpredictable.⁶⁸ In this situation, P_{pl} cannot be assumed to be directly related to PAW .⁶⁹ If lung compliance is low and chest wall compliance is high, very little of the alveolar pressure will be transmitted to the pleural space and vice versa. In healthy individuals the chest wall and lung compliances are equal, and thus the increase in pleural pressure is roughly equal to half of the applied PEEP (e.g., 5 cm H₂O pressure if the PEEP is 10 cm H₂O pressure).

However, if lung compliance is much less than chest wall compliance (e.g., in a thin patient with severe ARDS), the pleural pressure will change minimally with PEEP. In contrast, if lung compliance is much greater than chest wall compliance (e.g., in a patient with emphysema and kyphoscoliosis), a much greater proportion of PEEP will be transmitted to the pleural space.

Plateau Pressures in Patients Receiving Positive-Pressure Mechanical Ventilation

In patients receiving positive-pressure mechanical ventilation, the plateau pressure is the distending pressure of the respiratory system at end inspiration, when there is no flow. When possible, plateau pressures should be limited to a maximum of 30 to 35 cm H₂O because higher pressures can damage the lung through overdistention. This recommendation is based in part on animal studies that show that pressures below this range seem to protect the lungs from injury.⁷⁰ There is also a physiologic basis for this practice because at TLC in a normal subject, the distending pressure across the lung (alveolar pressure minus pleural pressure) is approximately 35 cm H₂O.⁷¹ Therefore limiting the plateau pressure to less than 35 cm H₂O should limit lung expansion to below TLC and not overdistend the lung. The use of low tidal volumes during mechanical ventilation for lung injury has led to improved clinical outcomes, presumably because of decreased alveolar distention and volutrauma.⁷² In a landmark study, tidal volumes were limited to 4 to 6 mL/kg of ideal body weight in an attempt to limit

lung overdistention.⁶⁵ However, others have argued that alveoli may become overdistended and undergo cyclic recruitment-derecruitment even with low tidal volumes in some patients,⁷³⁻⁷⁵ whereas ultralow tidal volumes (4 mL/kg of ideal body weight or less) may decrease this phenomenon further.⁷⁶

Although limiting plateau pressures and tidal volumes during mechanical ventilation has demonstrated some benefit in decreasing ventilator-associated lung injury, there is no clear limit below which further decreases will not improve outcomes.⁷⁷ This may be because neither plateau pressure nor tidal volume measurements account for the effect of pleural pressure on lung mechanics. During mechanical ventilation, plateau pressure is often used as a surrogate for transpulmonary pressure (pressure used to distend the lung), when it is actually a measure of transrespiratory system pressure. When lung compliance is much less than chest wall compliance, this is a reasonable assumption, because during mechanical ventilation, pleural pressure will not be substantially greater than body surface pressure. However, in conditions in which the chest wall is stiff (e.g., obesity, after abdominal surgery), the plateau pressure may substantially overestimate the distending pressure of the lung, because pleural pressure may be much greater than body surface pressure.⁷⁸ Indeed, some investigators have suggested that measurement of pleural pressure (with an esophageal balloon) could be useful in titrating mechanical ventilation in ARDS.⁷⁹

Stress and Strain

A discussion of the mechanics of stress and strain is available online.

THE RESPIRATORY SYSTEM IN DYNAMIC CONDITIONS

The work to distend the chest wall and lung during inhalation is stored as potential energy (elastic work). Work also must be done to overcome the inertia of the gas (which is negligible when breathing air at normal breathing frequency and atmospheric pressures) and nonelastic resistance (resistive work), which cannot be stored, but is dissipated as heat. Resistive work has two components that must be considered.

RESISTIVE WORK DUE TO GAS FLOW THROUGH AIRWAYS

When gas flows through an airway, frictional and viscous forces cause energy loss and a pressure drop along the airway. The extent of this pressure drop is dependent on the resistance to gas flow, physical properties of the gas (e.g., density and viscosity), and the nature of flow (laminar versus turbulent).

Laminar versus Turbulent Flow

The frictional drop is least with pure laminar flow, in which gas molecules travel in a straight line. The velocity profile of the gas is parabolic, with the molecules closer to the wall

To an engineer, stress is the net difference between forces acting on a body (in this case, the lung parenchyma). From the point of view of lung mechanics, stress reflects the difference between distending forces (for example, alveolar pressure) and collapsing forces (the pleural pressure in this case), and stress is therefore represented by the transpulmonary pressure.⁸⁰

The deformation of a structure by stress is called “strain,” which is defined as the change in size or shape compared to the structure’s initial shape or volume. That is:

$$\text{Strain} = \Delta V / \text{FRC}$$

For example, if a lung is inflated with a 500-mL tidal volume from an initial FRC of 1500 mL, the strain associated with this is 0.33 (500 mL/1500 mL). The recommendation of a specific tidal volume for lung-protective ventilation is predicated on the assumption that there is a uniform amount of lung able to receive the inspired volume. This volume is the amount of aerated lung at end expiration—the FRC. Underlying this is the assumption that the FRC can be predicted by ideal body weight—an assumption that is not correct in injured lungs.⁸¹ It is therefore understandable that, given the same ideal body weights and tidal volume prescriptions, two patients with ARDS might have significantly different lung strain if they have different

FRCs. It therefore may be prudent to attempt to minimize strain during mechanical ventilation by measuring FRC and titrating tidal volume to this assessment rather than ideal body weight. Indeed, there is some evidence that maintaining strain less than 1.5 to 2 reduces markers of lung parenchymal injury.⁸² From a practical point of view, however, it is time consuming and laborious to measure FRC in a serial fashion. Although there are commercially available FRC measurement systems, either as stand-alone systems or integrated into mechanical ventilators, the cost of these systems is not insignificant. Fortunately, it is possible to estimate strain from measurements of stress because the two values are linked by a constant (the specific elastance of lung [EL_{spec}]) such that:

$$\text{Strain} = \text{Stress} / EL_{\text{spec}}$$

Fortunately, the value of EL_{spec} is fairly constant throughout health and disease, with a value of approximately 13 cm H₂O.^{83,84} Thus by measuring stress, strain may be inferred (i.e., approximately one thirteenth of stress). Unfortunately, neither of these measures accounts for the local heterogeneity of mechanical characteristics found in injured lung. It is therefore possible that susceptible lung units are subject to critically injurious forces even when global measures of stress and strain appear acceptable.⁸⁵

Figure 5-16 Laminar versus turbulent flow. Schematic depiction of the spatial and velocity profiles of gas molecules with laminar (A) and turbulent (B) flow. The velocity of the gas molecules is proportional to the length of the arrows. During turbulent flow there is chaotic molecular movement between lamina that results in ever-greater pressure being required to achieve incremental flow. C, Note the nonlinear pressure-flow relationship with turbulent flow and the lower flows in the setting of turbulent than laminar flow at the same pressure.

traveling slower than molecules in the center of the airway (Fig. 5-16). When gas flow is laminar, the flow is proportional to the pressure gradient (ΔP) along the airway and inversely proportional to resistance (R).

$$\text{Flow} = \Delta P / R$$

For a straight airway under conditions of laminar flow, resistance of a tube is related to viscosity, length, and radius of the tube by the Poiseuille equation:

$$\text{Resistance} = 8 \times \text{length} \times \text{viscosity} / (\pi \times \text{radius}^4)$$

Because of this relationship, flow through a tube is dramatically affected by even small changes in tube diameter because resistance increases as the fourth power of the radius (i.e., reducing the radius by half causes a 16-fold increase in resistance).

In turbulent flow the orderly pattern of gas molecule movement is replaced with a haphazard pattern (see Fig. 5-16). When gas flow is turbulent, the flow is proportional to the square root of the pressure gradient (as opposed to a linear relationship to the pressure gradient itself in the case of laminar flow).⁶⁶

$$\text{Flow} = \text{constant} \times (\Delta P)^{1/2}$$

Stated another way, the pressure drop for turbulent flow is much greater than for laminar flow, with the drop along the airway proportional to the square of flow as follows:

$$\Delta P = \text{constant} \times \text{flow}^2$$

Because resistance is defined as the pressure gradient divided by the flow rate, the “resistance” for turbulent flow is not constant but increases in proportion to flow.

In contrast to laminar flow, turbulent flow is inversely proportional to gas density but is not affected by viscosity. The driving pressure required is proportional to the fifth power of the radius of the airway.

The Reynolds Number

The *Reynolds number* (Re) is a dimensionless coefficient that predicts whether flow through an unbranched airway will

be predominantly laminar, turbulent, or mixed. The equation is as follows:

$$\text{Re} = \rho dV / \mu$$

where ρ is the gas density, d is the diameter of the airway, V is the mean gas velocity, and μ is the viscosity. In general, a value of Re of less than 2000 is associated with laminar flow, whereas a value greater than 4000 is associated with predominantly turbulent flow.⁶⁴ Intermediate values are associated with mixed flow patterns.

The cross-sectional diameter of the central airways (e.g., trachea) is much greater than the smaller peripheral airways (e.g., bronchioles). However, the entire cross-sectional area of the peripheral airways is much greater than that of the central airways. Therefore, as gas moves from the peripheral to the central airways during exhalation, the gas velocity increases as the airway diameter increases. This results in predominantly turbulent flow in the larger central airways (except at very low flow rates) and predominantly laminar flow in the periphery.

Clinical Effects of Heliox

Heliox is a mixture of oxygen and helium. Heliox has a density less than air and a viscosity greater than air. For instance, a mixture of 20% oxygen and 80% helium has a density of 0.33 relative to air and a viscosity of 1.08 relative to air.⁶⁴ Because gas density influences the resistance during turbulent flow, this gas mixture can be especially beneficial in patients who have upper airway narrowing (e.g., partial tracheal obstruction).⁸⁶ Substituting heliox for air or oxygen reduces gas density, lowering the Reynolds number, and helps to convert turbulent to laminar flow. This reduces the pressure required to move gas through the airways and diminishes the work of breathing, unloading the respiratory muscles.

Heliox may be useful in patients with asthma or COPD, although this is controversial.⁸⁷⁻⁸⁹ The reason for a beneficial effect is unclear, because flow in the smaller bronchioles, which contribute most of the increased airways resistance in asthma and COPD, should be laminar rather than turbulent. The effectiveness of heliox in asthma might be related to narrowing of large central airways from secretions and conversion of flow from turbulent to laminar in larger airways. Heliox might also be beneficial in vocal cord dysfunction for a similar reason.

Flow Limitation

In a normal subject, increasing expiratory effort will increase air flow until a threshold is reached. Once this effort threshold is exceeded, expiratory flow will not increase despite a further increase in effort, resulting in flow limitation as opposed to pressure limitation⁹⁰ (Fig. 5-17). In contrast, patients with very poor effort or marked expiratory muscle weakness may be unable to generate high expiratory pressures, resulting in pressure limitation before flow limitation is reached. Flow limitation is an important concept; if flow were not relatively effort independent, measures such as forced expiratory volume in 1 second would have little utility in monitoring patients because variable effort would result in poorly reproducible results.

Figure 5-17 Expiratory flow limitation. Left, The expiratory flow-volume curve for a normal subject. Maximal flow rates are plotted against their corresponding volumes at A, B, and C and define the maximal expiratory flow-volume curve. Right, Three isovolume pressure-flow curves for the same subject. Once a threshold transpulmonary pressure is achieved, no increase in flow is seen. TLC, total lung capacity. (From Hyatt RE: Forced expiration. In Macklem PT, Mead J, editors: *Handbook of physiology*. Section III. The respiratory system. Vol 3: Mechanics of breathing, part 1. Bethesda, MD, 1986, American Physiological Society, pp 295–314.)

Figure 5-18 Equal pressure point theory. At the equal pressure point (*), pressure inside the tube is equal to the pressure outside the tube (pleural pressure [Ppl]) due to pressure drop related to flow-resistive losses from alveolus to *. Downstream (mouthward) from the equal pressure point, the airway is compressed. Once an equal pressure point develops, increasing expiratory effort, although increasing the alveolar pressure (Palv), simply increases the downstream compression and causes no increase in flow. Pao, airway opening pressure.

Flow is limited because of the properties of the airways. For simplicity, the airways are often likened to a rigid tube, but, in reality, the airways are partially collapsible. During inhalation, pleural pressure is negative, and the intrathoracic airways tend to be pulled open. During forced exhalation, pleural pressure becomes positive, increasing pressure around the intrathoracic airways and predisposing to their collapse.

Several theories have been developed to explain the limitation of flow at below maximal effort.

Equal Pressure Point Theory (Fig. 5-18). Consider the respiratory system depicted as a balloon (lung) inside a box (chest wall) connected by a tube that extends through the box (intrathoracic airway). The pressure inside of the lung is equal to the pleural pressure (created by expiratory muscle activation) plus the recoil pressure of the lung. As air travels down the airway, pressure in the airway will decrease, predominantly because of frictional losses. A point is eventually reached where the pressure inside the airway equals the pleural pressure outside the airway, termed the *equal pressure point* (EPP).^{91,92} Downstream (mouthward) of this EPP, the pressure inside the airway

drops below the pressure outside the airway, and the airway tends to collapse. Further increases in effort will increase pleural pressure, but this simply causes greater narrowing of the airway downstream of the EPP, so that flow remains constant. Under these conditions, the airway acts as a Starling resistor; flow is now not proportional to the difference between alveolar and mouth pressure but rather is proportional to the difference between alveolar pressure and pressure at the EPP. In this case, the pressures downstream from the EPP have no effect on expiratory flow.

This concept can be mathematically expressed as follows: Because

$$\text{Alveolar pressure} = \text{Pleural pressure} + \text{Elastic recoil pressure of the lung}$$

and

$$\text{Pressure at EPP} = \text{Pleural pressure}$$

and

$$\text{Driving pressure for flow} = \text{Alveolar pressure} - \text{Pressure at EPP}$$

therefore

$$\begin{aligned} \text{Driving pressure} &= (\text{Pleural pressure} \\ &\quad + \text{Lung recoil pressure}) \\ &\quad - \text{Pleural pressure} \\ &= \text{Lung recoil pressure} \end{aligned}$$

Therefore further increases in effort will increase alveolar and EPP pressure equally, resulting in no difference in driving pressure and airflow.

The Bernoulli Effect and Wave Speed Theory. The Bernoulli effect provides an alternative explanation for flow limitation.⁹³ As gas flows through a tube, the lateral pressure exerted by the gas is less than the pressure driving flow by an amount proportional to the velocity of the gas. If the tube is collapsible, as gas velocity increases, there is a tendency for the tube to collapse, leading to a reduction in airflow.

The wave speed theory is yet another explanation for expiratory flow limitation.⁹⁴ When fluid is pushed through a collapsible tube, a pressure wave is propagated along the wall of the tube. The speed of this pressure wave is dependent on the characteristics of the tube and the density of the gas rather than the driving pressure. The velocity of the gas in the tube cannot exceed the velocity of the pressure wave, and thus the velocity of this wave represents a “speed limit” for the gas in the tube.

Interestingly, the maximal flow of gas derived using the Bernoulli effect and wave speed theory are identical, as shown by the following formula:

$$\text{Maximal flow} = A\sqrt{(A/\text{gas density})(dP/dA)}$$

where A represents the cross-sectional area of the airway wall and dP/dA represents the slope of the relationship between changes in transmural pressure of the tube and changes in tube area. Therefore maximal flow should increase if the tube area increases, gas density decreases, or tube stiffness increases.

The EPP mechanism might be more important at lower lung volumes and flows, whereas the Bernoulli and wave

Table 5-1 Components of Respiratory System Resistance

	Mouth/ Pharynx	Large Airways	Small Airways	Lung Tissue	Chest Wall	Total
Resistance (cm H ₂ O/ L/sec)	0.5	0.5	0.2	0.2	1.2	2.6
% of resistance	19	19	8	8	46	100

speed effects might predominate at higher volumes and flows.⁹⁵

OTHER RESISTIVE WORK

Besides the elastic work done by the respiratory muscles on the lung and chest wall, an additional component of work is expended to overcome what is sometimes called “tissue resistance.” This is energy required to distort the lung and chest wall during inhalation and is dissipated as heat.

The breakdown of the various components of the total resistive work is shown in [Table 5-1](#).

Equation of Motion

During ventilation, gas moves along a pressure gradient (ΔP). This pressure difference must be created by either the patient's own muscular efforts (P_{mus}) or a mechanical ventilator (P_{AW}). The energy loss represented by this pressure drop is used to overcome resistance to airflow and tissue deformation, to expand the lungs and chest wall, and to overcome gas inertance (resistance to changes in velocity or direction of gas flow). The first-order linear equation of motion describes the relationship between these variables as:

$$\begin{aligned}\Delta P &= P_{\text{AW}} + P_{\text{mus}} \\ &= \dot{V}R + V_T/C + I \ddot{V} + P_{\text{EEPi}} + P_{\text{EEPset}}\end{aligned}$$

Where \dot{V} is gas flow, R is resistance, $\dot{V}R$ is the work done by pressure to overcome airflow and tissue resistance, V_T is tidal volume, C is compliance, V_T/C is the work done by pressure to expand the respiratory system, and $I \ddot{V}$ (I represents inertance, and \ddot{V} represents acceleration) is the pressure needed to overcome gas inertance. P_{EEPi} represents intrinsic positive end-expiratory pressure, and P_{EEPset} represents the positive end-expiratory pressure created by the ventilator. In most practical situations involving adults, inertance is ignored because it makes such a small contribution to work. In patients with either trapped gas due to P_{EEPi} or clinician-instigated PEEP (P_{EEPset}), the PEEP should be accounted for in this equation.

INTRINSIC PEEP DURING POSITIVE-PRESSURE VENTILATION OF COPD

An appreciation of the dynamics of the respiratory system aids in understanding clinical scenarios, such as patients with COPD who are treated with positive-pressure ventilation for respiratory failure.⁷⁷ Because lung resistance and

Figure 5-19 Failure to trigger the ventilator in a patient with COPD. Graph of flow (\dot{V}) and esophageal pressure over time in a patient with COPD and intrinsic positive end-expiratory pressure (PEEP) receiving positive-pressure mechanical ventilation. The patient has made two attempts (\dagger) at triggering inspiration but could not, because of the intrinsic PEEP. When pleural pressure is sufficiently negative to exceed the ventilator's threshold (dotted line), this triggers the ventilator (*) and a breath is provided. Note the failure of expiratory flow to reach 0 before a triggered breath.

compliance are variable in these patients, their lungs contain individual lung units with long time constants, and there may be insufficient time for the lungs to empty completely at the end of exhalation. Heterogeneity of time constants will result in heterogeneity of emptying times. If insufficient time is allowed for complete emptying of lung units, the result will be a positive mean alveolar pressure in the alveolus at the end of exhalation. This has been termed “intrinsic PEEP.”

PEEP has a number of adverse consequences. First, the positive pressure at end-expiration increases intrathoracic pressure and can reduce venous return, causing hypotension.⁶⁶ Second, the high end-expiratory alveolar pressure acts as an inspiratory threshold load. That is, in order to generate a negative pressure that is great enough to trigger the ventilator and initiate inspiratory flow, the inspiratory respiratory muscles must exert adequate pressure to counteract the intrinsic PEEP pressure and reduce alveolar pressure to a subatmospheric value before inspiratory flow can be initiated.⁹⁶ Third, high intrinsic PEEP may lead to inspiratory efforts that are ineffective in triggering the ventilator if the respiratory muscles cannot reduce alveolar pressure to less than the applied PEEP⁹⁷ ([Fig. 5-19](#)). This may lead to patient-ventilator dyssynchrony and discomfort. Fourth, intrinsic PEEP and the consequent hyperinflation of the lung at end-expiration place the inspiratory muscles at a mechanical disadvantage,³⁶ which can lead to failure of weaning from mechanical ventilation.

Intrinsic PEEP can be treated by increasing the applied PEEP from the ventilator, which may improve patient-ventilator synchrony.⁹⁸ Increasing applied PEEP will not reduce expiratory flow if the applied PEEP is less than the level of intrinsic PEEP because these patients are usually flow rather than pressure limited. However, increasing the applied PEEP will decrease inspiratory muscle work and facilitate ventilator triggering.

The end-expiratory occlusion method is commonly used to measure intrinsic PEEP ([Fig. 5-20](#)) (static intrinsic PEEP). The expiratory line in the ventilator is occluded at the end of an exhalation.⁹⁹ If intrinsic PEEP is present, airway pressure will increase until a plateau is reached (usually 4 to 5 seconds). This value represents an “average” measure of

Figure 5-20 Measurement of intrinsic positive end-expiratory pressure (PEEP) while on a ventilator. Flow (\dot{V}) and airway pressure (P_{ao}) over time. The arrow represents the point at which the expiratory line is occluded, leading to an increase in measured pressure that represents the degree of intrinsic PEEP.

intrinsic PEEP after redistribution of volume from some alveoli to others depending on regional compliance (pendelluft). Pendelluft is the transient movement of gas from one lung unit to another.

Alternatively, intrinsic PEEP may be measured under dynamic conditions (dynamic intrinsic PEEP) when the patient is spontaneously breathing.⁹⁹ This can be done by inserting an esophageal balloon to measure pleural pressure and measuring the reduction in pleural pressure necessary to initiate inspiratory flow. Dynamic intrinsic PEEP is usually less than that measured under static conditions because it reflects the region of the lung with the least amount of intrinsic PEEP, as opposed to the average amount of intrinsic PEEP.

Intrinsic PEEP is not limited to patients on mechanical ventilation. Spontaneously breathing patients who have COPD can develop positive end-expiratory alveolar pressure, especially when they increase their inspiratory rate during exertion, a phenomenon that has been termed “dynamic hyperinflation.” This increases work of breathing (see later discussion) and contributes to exercise limitation in these patients.

Measurement of Static Compliance and Resistance during Mechanical Ventilation

In the intensive care unit, measurement of respiratory system compliance and resistance can be helpful in assessing the timing for weaning from mechanical ventilation or determining the reasons for failure of a spontaneous breathing trial. Normal respiratory system compliance in a supine subject is approximately 100 mL/cm H₂O. A markedly decreased compliance should prompt a search for causes of reduced lung (e.g., edema) and/or chest wall compliance (abdominal distention) that might be potentially reversible. Similarly, a markedly increased resistance should prompt a search for reversible causes, including bronchospasm, or partial obstruction of the endotracheal tube from kinking or secretions.

Calculation of compliance and resistance should be performed with a square wave flow pattern after an inspiratory pause. Patients need to be relaxed or paralyzed to obtain accurate measurements. If respiratory efforts are present, airway pressures may not reflect transmural pressures across the respiratory system but rather may reflect pleural pressures.

Figure 5-21 Ventilator mechanics. Point A is the peak pressure (40 cm H₂O). Point B is the plateau pressure (35 cm H₂O). Point C is the inspiratory pause.

Consider a paralyzed sedated patient treated with positive-pressure mechanical ventilation in the assist-control mode. The changes in flow, volume, and pressure over time are shown in Figure 5-21. Assume a constant inspiratory flow rate (1 L/sec) and a tidal volume of 500 mL (0.5 second inspiratory time). Because flow is constant, volume increases linearly over time. Peak pressure is 40 cm H₂O, plateau pressure is 35 cm H₂O, and PEEP is set at 5 cm H₂O.

Using the balloon-and-tube analogy of the respiratory system (see Fig. 5-4), the components of pressure required are as follows:

$$\begin{aligned} \text{Total pressure} = & \text{Pressure to distend respiratory system} \\ & + \text{Pressure to maintain gas flow} \\ & + \text{Inertial pressure losses} \end{aligned}$$

Because the inertial component can be ignored at the respiratory rates commonly used:

$$\begin{aligned} \text{Total pressure} = & \text{Pressure to distend respiratory system} \\ & + \text{Pressure to maintain gas flow} \\ = & \Delta \text{Volume}/\text{compliance} + \text{Flow} \times \text{resistance} \end{aligned}$$

The difference between plateau pressure (measured during an inspiratory hold) and PEEP represents the pressure required to distend the respiratory system at 0 flow.

Therefore,

$$\text{Plateau pressure} - \text{PEEP} = \Delta \text{Volume}/\text{compliance}$$

Rearranging the equation yields:

$$\text{Compliance} = \Delta \text{Volume}/(\text{Plateau pressure} - \text{PEEP}) \quad [1]$$

The difference between peak pressure (point A in Fig. 5-21) and plateau pressure (point B in Fig. 5-21) represents the pressure required to overcome resistance of the respiratory system (this predominantly represents flow resistance, but also includes contributions from tissue resistance, stress relaxation, and pendelluft).

Therefore,

$$\begin{aligned} \text{Peak pressure} - \text{PEEP} = & \Delta \text{Volume}/\text{compliance} \\ & + \text{Flow} \times \text{resistance} \end{aligned} \quad [2]$$

Rearranging Equations 1 and 2:

$$\text{Peak pressure} - \text{Plateau pressure} = \text{Flow} \times \text{resistance}$$

Because flow is known:

$$\text{Resistance} = (\text{Peak pressure} - \text{Plateau pressure}) / \text{Flow}$$

Going back to our patient:

$$\text{Compliance} = 500 \text{ mL} / (30 \text{ cm H}_2\text{O}) = 16.7 \text{ mL/cm H}_2\text{O}$$

$$\text{Resistance} = 40 - 35 \text{ cm H}_2\text{O} / \text{L/sec} = 5 \text{ cm H}_2\text{O/L/sec}$$

In other words, the patient's compliance is severely reduced, suggesting an extremely stiff respiratory system. However, the resistance is relatively low. By placing an esophageal catheter to estimate pleural pressure, one could ascertain the separate contributions of the lung and the chest wall to the reduced respiratory system compliance, further clarifying the source of the impediment to weaning.

ENERGETICS AND WORK OF BREATHING

When a force is applied to an object over a distance, energy is required; the work done is equal to:

$$\text{Work} = \text{force} \times \text{distance}$$

Similarly, because pressure is force over an area and volume is an area multiplied by a distance, work in a fluid system may be defined as the integral of applied pressure over a change in volume:

$$\text{Work} = \int P dV$$

During inspiration, work must be performed to distend the respiratory system (elastic work), which is stored as potential energy. Also, nonelastic work must be done to generate flow through the airways (to overcome resistance to gas flow), to overcome lung and chest wall tissue resistance, and to accelerate gas (to generate the inertial component). This work cannot be stored as potential energy and is dissipated as heat. The inertial component is minimal and is usually ignored in measuring total work.

MEASURING WORK OF BREATHING DONE BY A POSITIVE-PRESSURE VENTILATOR IN A PARALYZED PATIENT

Consider a paralyzed patient receiving positive-pressure mechanical ventilation, such that the entire work of breathing is performed by the ventilator (Fig. 5-22). On a volume-pressure plot, pressure applied to the airway will track to the right of the static volume-pressure curve of the respiratory system because additional pressure is required to overcome resistive forces. The blue shaded area represents the elastic work done by the ventilator during one inhalation, and the gray shaded area represents the resistive work that was expended to generate flow and overcome tissue resistance. With exhalation, the stored elastic energy can be used to deflate the lungs, so that exhalation is normally a passive process. Increases in resistance or decreases in compliance can markedly increase the work of breathing.

Figure 5-22 Work of breathing during mechanical ventilation. Consider a paralyzed patient receiving one tidal breath while on positive-pressure mechanical ventilation (point A to point B). The *diagonal blue line* represents the volume-pressure curve of the static respiratory system; the *shaded blue area* to the left of this line thus represents the elastic work done during the inflation. This work can be stored as potential energy and can be used during exhalation. The *gray shaded area* to the right of the line represents the resistive work done.

Figure 5-23 Work of breathing during spontaneous breathing (Campbell diagram). A portion (from functional residual capacity [FRC] to FRC plus tidal volume) of the volume-pleural pressure curves of the lung and relaxed chest wall are shown. Consider a patient taking a spontaneous breath from FRC (point A) with a volume equal to the height of the *double-headed arrow* (point B). In order to overcome elastic forces of the lung and chest wall, the inspiratory muscles must exert a force equal to the horizontal distance between the chest wall and lung volume-pleural pressure curves. Thus the entire elastic work done will be equal to the *blue shaded area*. Furthermore, resistive work must also be done, requiring the inspiratory muscles to generate an even greater negative pleural pressure. This is indicated by the *gray shaded area*. The total work done will be the sum of both areas.

MEASURING WORK OF BREATHING IN A SPONTANEOUSLY BREATHING PATIENT

In a spontaneously breathing patient, work is performed by the inspiratory muscles rather than a ventilator. Graphing the pressure-volume characteristics of the lung and chest wall against pleural pressure is useful in illustrating the work performed by the inspiratory muscles (Fig. 5-23). During inspiration, pleural pressure decreases to expand the lungs (see Fig. 5-23). The distance between the two curves at any given lung volume represents the pressure the inspiratory muscles must exert to overcome elastic forces of the lung and chest wall. The blue shaded area thus represents the elastic work of breathing against the lung and chest wall. To overcome the resistive forces, additional pressure and work are required, as indicated by the gray shaded area.

Under normal conditions, exhalation is passive because the stored potential energy from elastic work is more than sufficient to overcome resistive work. However, in the presence of severe airflow obstruction (e.g., an asthma attack), the necessary resistive work may exceed this stored energy, requiring active generation of force by expiratory muscles and additional work for exhalation.

OXYGEN COST OF BREATHING

The oxygen cost of breathing is an indicator of the total amount of energy required by the respiratory muscles for ventilation. At rest, the oxygen cost of breathing is low, 0.25 to 0.5 mL/L of ventilation, or 1% to 2% of total body oxygen consumption. However, at maximal exercise in normal subjects, the oxygen cost of breathing represents approximately 10% to 15% of total oxygen consumption.¹⁰⁰ The oxygen cost of breathing can increase markedly as minute ventilation increases (eFig. 5-1).

Patients with COPD have an increased oxygen cost of breathing as a function of ventilation (see eFig. 5-1). This may be related to a combination of increased work of breathing and decreased efficiency due to dynamic hyperinflation. Dynamic hyperinflation is an increase in end-expiratory lung volume that results when patients with airflow obstruction develop intrinsic PEEP due to long time constants for gas distribution in the lungs and the increased respiratory rate they often exhibit.¹⁰¹

In addition, tonic inspiratory muscle activity at end-expiration contributes to dynamic hyperinflation. Although this dynamic increase in lung volume can have a beneficial effect by dilating intraparenchymal airways to decrease the resistive work, the end-expiratory alveolar pressure acts as an inspiratory threshold load, which increases the work of breathing. Furthermore, the mechanical efficiency of the inspiratory muscles is compromised by hyperinflation because the zone of diaphragmatic apposition is reduced and the inspiratory muscles are shorter than the optimal length for force generation. The efficiency of breathing (defined as the ratio between the rate of mechanical work accomplished and the rate of energy consumed) may be further diminished if postural or other stabilizing muscles (trunk, neck, shoulder) need to be recruited.

Key Points

- An understanding of the mechanical properties of the lung and chest wall under static and dynamic conditions is important for appreciating the determinants of lung volumes and expiratory flows under normal and pathologic conditions.
- Under conditions of laminar flow, flow is directly proportional to the pressure difference along the path of flow. Under conditions of turbulent flow, flow is directly proportional to the square root of the pressure difference. For turbulent flow the pressure drop is greater for any given flow than for laminar flow.
- In turbulent flow the substitution of a mixture of helium and oxygen can lower airway resistance because its gas density is less than air or oxygen. Turbulent flow can be present in upper airway obstruction

and perhaps in asthma if there is large-airway narrowing.

- The majority of the elastic recoil of the lung is due to surface forces generated by fluid lining the alveoli.
- The unique properties of surfactant help to reduce surface tension and stabilize alveoli at low lung volumes, thereby preventing their collapse.
- At functional residual capacity (relaxation volume), the outward recoil pressure of the chest wall is balanced by the inward recoil of the lung. Total lung capacity is determined by the balance between the maximal inspiratory pressure generated by the respiratory muscles and the opposing pressure generated by the inward recoil of the lungs and chest wall. In young subjects, residual volume is determined by the balance of pressure generated by the expiratory muscles, the minimal inward recoil of the lung, and the opposing pressures generated by the outward recoil of the chest wall. In older subjects or patients with obstructive lung disease, residual volume is not determined by this balance of forces but is rather determined by airway closure.
- Measuring respiratory system resistance and compliance can be easily accomplished in ventilated patients and is useful for assessing reasons for difficulty in weaning from the ventilator.
- In ventilated patients the proportion of the applied airway pressure that is transmitted to the pleural space is dependent on the ratio of lung and chest wall compliance. Knowing the change in pleural pressure is important because it influences venous return. Insertion of an esophageal balloon may be needed to measure the actual change in pleural pressure produced by applied airway pressure.
- In patients with airflow obstruction who are treated with positive-pressure ventilation, dynamic hyperinflation (intrinsic positive end-expiratory pressure) can lead to hemodynamic compromise, increased work of breathing, an inspiratory threshold load, mechanical inefficiency of the diaphragm, and patient-ventilator asynchrony.

functions include direct lung vascular barrier regulation, participation in the initiation and resolution of inflammatory responses and the processing of mediators before delivery to the systemic circulation.

INTRODUCTION

The pulmonary circulation is interposed between the right and left ventricles with the following primary functions: (1) to deliver the entire cardiac output under low pressure from the right ventricle to the pulmonary microvessels and, in the process, to exchange carbon dioxide for oxygen across the alveolar-capillary membrane; (2) to act as a source of production, release, and processing of humoral mediators; and (3) to serve as a barrier to the exchange of fluid and solutes and thus maintain lung fluid balance. The morphologic characteristics of the pulmonary circulation are ideally adapted for these functions. Nearly the entire cardiac output is brought into contact with alveolar gas at the 1- to 2- μ m-thick alveolar-capillary membrane for approximately 0.75 to 1 second. This juxtaposition of capillaries with alveoli provides the vast surface area needed for effective gas exchange: approximately 70 m² (two thirds the area of a tennis court). The structural arrangement is such that the distance through which oxygen and carbon dioxide must diffuse between gas and blood is approximately one tenth the distance of diffusion in peripheral tissues. (Additional information about the anatomy of the pulmonary circulation is found in Chapter 1, and about the physiologic factors that govern the distribution of blood flow in Chapter 4.)

The pulmonary circulation has important additional functions beyond its role in gas exchange. The microvessels exchange solutes and water, and the mechanisms regulating the balance of fluid and solutes in extravascular spaces of the lung are critical to the understanding of the pathophysiology of pulmonary edema (see section “Pathogenesis of Pulmonary Edema” and Chapter 62). The pulmonary vascular endothelium, the monolayer of cells that lines all vessels, is a multidimensional tissue whose specialized

ANATOMY

The pulmonary circulation begins at the pulmonary valve, marking the vascular exit from the right side of the heart, and extends to the orifices of the pulmonary veins in the wall of the left atrium, which marks the entrance into the left side of the heart. The pulmonary circulation includes the pulmonary trunk (also called the “right ventricular outflow tract”), the right and left main pulmonary arteries and their lobar branches, intrapulmonary arteries, large elastic arteries, small muscular arteries, arterioles, capillaries, venules, and large pulmonary veins. Because of this heterogeneity and differences in physiologic behavior, the vessels of the pulmonary circulation are subdivided on a functional basis into *extra-alveolar vessels* and *alveolar vessels*. In addition, the small vessels that participate in liquid and solute exchange are often collectively termed the “pulmonary microcirculation.” The anatomic boundaries of the extra-alveolar and alveolar vessels and the microcirculation are undefined and likely depend on conditions such as lung volume and levels of intrapleural and interstitial pressures.

Additional information on the anatomy of the pulmonary circulation as well as the bronchial circulation can be found in the online version of the text (eFig. 6-1) and in Chapter 1.

PULMONARY HEMODYNAMICS

PULMONARY VASCULAR PRESSURES

Pressure and flow are highly pulsatile throughout the pulmonary circulation. Although the pressure pulsatility

Additional information on the anatomy of the pulmonary circulation as well as the bronchial circulation can be found in Chapter 1.

GENERAL DESIGN

The *pulmonary trunk* arises from the infundibulum of the right ventricle through the orifice of the pulmonary valve. The trunk, which is approximately 3 cm in diameter and 5 cm in length, lies entirely within the pericardium, as does the adjacent ascending aorta. The pulmonary trunk passes upward and backward into the concavity of the aortic arch, where it divides into the two main pulmonary arteries.

The *right main pulmonary artery* is slightly larger and longer than the *left main pulmonary artery*, and both vessels show little variation in either position or mode of branching. The right main artery divides into two branches: a larger lower branch that supplies the right middle and lower lobes, and a smaller upper branch that supplies the upper lobe. On the left the main artery lies above the main bronchus until the first branch arises and subsequently traverses in a downward direction behind the bronchus. The arterial branches supplying the lobes of both the right and left lungs, in contrast, show considerable variation. The pulmonary arteries and bronchi are enclosed in the same connective tissue sheath and generally branch together until reaching the smallest units: the alveoli and capillaries.¹ The pulmonary veins are also enveloped in connective tissue sheaths that are distinct from those enclosing the arteries and bronchi.²

The pulmonary arterial circulation has two sets of branches: the conventional arteries that accompany airways, and supernumerary arteries that travel alone and are commonly of smaller dimensions. The supernumerary arteries are entirely intrapulmonary, emerging from the main arterial channels at approximately right angles as far in the periphery as the end of respiratory bronchioles. These branches provide approximately 25% of the total cross-sectional area of the pulmonary arterial bed near the hilum and approximately 40% of the total cross-sectional area of the peripheral pulmonary arterial bed. The supernumerary arteries that are present at birth are mainly those that lead to terminal respiratory units, the structures distal to terminal bronchioles that participate in gas exchange (respiratory bronchioles, alveolar ducts, and alveoli).³ Extensive growth of conventional and supernumerary branches accompanies the development of alveolar ducts and alveoli during the first 18 months of life.^{4,5} Whereas the appearance of conventional arteries virtually ceases at 18 months, supernumerary arteries continue to increase in number up to approximately age 8 years as new alveoli are formed. Supernumerary vessels undoubtedly serve as an auxiliary arterial supply to the capillary beds of the terminal respiratory units and thus constitute a critical source of collateral blood flow to sites of gas exchange.

The *pulmonary vascular resistance* is approximately one tenth the systemic peripheral vascular resistance. This unique low-resistance characteristic of the pulmonary circulation is the result of specialized morphologic features of pulmonary arteries and veins combined with a normally low vascular tone. Both pulmonary arteries and veins have

significantly less smooth muscle content than do vessels of the same diameter in other organs, and the smooth muscle is distributed less evenly than in systemic microvessels.⁶ Pulmonary arteries exhibit more smooth muscle than pulmonary veins and represent the main sites of constriction in response to vasoactive mediators.⁷

In humans the larger pulmonary arteries (>1 to 2 mm in diameter) are largely elastic. The *elastic pulmonary arteries* contain distinctive layers of elastic fibers embedded in a coat of smooth muscle cells. In fact, the pulmonary artery trunk, its main branches, and all extra-alveolar pulmonary arteries are of the elastic type. Arteries gradually become more muscular at diameters of greater than 2 mm followed by progressively less muscularization as diameter decreases to below 100 μm .^{8,9} The smooth muscle is unevenly distributed in the medial layer of the vessel wall in a way that is distinct from the thick circumferential distribution of smooth muscle in systemic arterioles. The *muscular pulmonary arteries* exhibit a thin medial layer of muscle embedded between well-delimited internal and external elastic laminae. Muscular pulmonary arteries lie within lung lobules and hence accompany the bronchioles. Although these vessels are designated by their muscular elements, the thickness of the muscle layer does not exceed approximately 5% of the external diameter of the vessel; any increase above this value connotes a pathologic state, as is clinically associated with conditions characterized by the presence of pulmonary arterial hypertension. As the smooth muscle content decreases in these vessels, the smooth muscle assumes a spiral orientation so that in a cross section of the vessel, the smooth muscle content is observed in only a portion of the vessel wall. These *pulmonary arterioles* are the terminal branches of the pulmonary arterial system. At their origin from muscular arteries, pulmonary arterioles contain a partial layer of muscle that gradually disappears until the vessel wall consists of only the endothelial monolayer and an elastic lamina. Pulmonary arterioles supply alveolar ducts and alveoli. In vessels smaller than 30 μm in diameter, smooth muscle is virtually absent. Chronic exposure to hypoxia causes extensive vascular remodeling, especially with significant increase in smooth muscle in small arteries.¹⁰ There is considerable species variability in pulmonary artery smooth muscle content and in the pulmonary hypertensive response to hypoxia.^{11,12}

Pulmonary veins have thinner walls than arteries because the muscular layer is not as well developed. Like the arterial system, the venous system is composed of both conventional and supernumerary veins. Small intrapulmonary venules successively unite to form increasingly larger veins, and finally a single *lobar vein* emerges from each lobe. Because the right upper and right middle lobar veins generally join together, the venous drainage from each lung terminates in a *superior pulmonary vein* and an *inferior pulmonary vein*. These four pulmonary veins then enter the left atrium through orifices in the upper posterior part of the chamber wall, although occasionally the two left veins join and enter through a common opening. The pulmonary vascular bed consists of a set of highly distensible vessels, a unique feature of this circulation in that pulmonary vessels are approximately seven times more compliant than peripheral systemic arteries¹³ due to the reduced smooth muscle content, fewer elastin and collagen fibers, and the lack of

tissue surrounding the small vessels. The resistance and distensibility functions of a pulmonary vessel overlap in the same vessel. Thus pulmonary vessels are able to accommodate relatively large increases in blood volume (as in exercise) in relation to same-sized systemic arteries and serve as an important blood volume reservoir. Smooth muscle cells are intercalated with the elastin and collagen fibers, thereby enabling reflex contraction of smooth muscle cells to vary the distensibility of the pulmonary vessels.¹⁴ In the microvasculature, pericytes, polymorphic and multifunctional cells that line the basal surface of endothelial cells, are involved in the production of the microvessel basal lamina¹⁵ and contribute to the contractile regulation of lung capillary permeability.¹⁶

Pulmonary vessels are innervated by cholinergic and sympathetic fibers, although the extent of the innervation is species specific and may vary from animal to animal.¹⁷⁻¹⁹ In comparison with peripheral vessels, the innervation pattern is sparse, with innervation most evident in the branching-off point of pulmonary arteries. Sympathetic and parasympathetic efferents are most prominent in small bronchioles and arterioles of the bronchial circulation, in contrast to pulmonary vessels,¹⁹ although the exact function remains incompletely defined. Recent studies have shown the densest innervation in the vessels in the bronchial walls, and that synaptophysin-immunoreactive terminals are formed by efferent axons of neurons arising from the intrapulmonary parasympathetic ganglia.²⁰ Furthermore, sympathetic pulmonary vascular neurons appear to be activated via arterial chemoreceptors in response to low PO_2 .²¹

BRONCHIAL CIRCULATION

A separate systemic circulation supplies blood flow to the airways from the carina to the terminal bronchioles. In addition, bronchial arteries provide nutritive flow to the lower trachea, airway nerves, and lymph nodes.^{22,23} The drainage of bronchial vessels into the pulmonary circulation and the large veins has a complex arrangement (eFig. 6-1). Interconnections have been demonstrated between bronchial vessels and precapillary, capillary, and postcapillary vessels of the pulmonary circulation.²⁴ Despite the fact that the normal adult lung remains viable without the bronchial circulation (as well as in the absence of innervation), as is the case in the transplanted lung, bronchial blood flow is critical in the lung development in the fetus and contributes to gas exchange in the presence of congenital cardiac anomalies. There is a striking increase in the size and number of bronchial arteries (due to angiogenesis) in lung disorders such as pulmonary fibrosis, lung carcinoma, and disorders characterized by pulmonary vascular occlusion.²⁵⁻²⁷ Neovascularization of the systemic circulation into the lung after pulmonary artery obstruction is now well recognized in multiple species.^{22,26}

There is considerable variation in the number and origin of the bronchial arteries in the human adult. One large cadaveric study found the majority of bronchial arteries arising directly from the aorta.²⁸ Over 40% of cadavers had two arteries branching to the left lung and one artery to the right lung. Occasionally the right bronchial artery originates from the first right intercostal artery. Variable numbers of smaller minor branches emerged from vessels in and

near the mediastinum and crossed into each lung. Upon entering the lung, bronchial arteries invest in connective tissue surrounding the bronchi and begin branching with two or three branches anastomosing to form a peribronchial plexus with an elongated and irregular mesh and accompany each subdivision of the conducting airways.

Blood flow to the lung via the bronchial circulation is low, presumed to be less than 3% of the cardiac output, but has never been measured accurately in humans. Canine studies indicate that bronchial blood flow to the left lung is approximately 1% of the cardiac output, with approximately 50% of this flow directed to the lung parenchyma and the remainder to the trachea and bronchi.²⁷ If bronchial blood flow in humans is similar to canine findings, total bronchial blood flow estimates to both lungs would be approximate 1% to 2% of the cardiac output.

Venous blood from capillaries supplied by bronchial arteries returns to the heart by two different pathways (see eFig. 6-1). True *bronchial veins* are found only at the hilum; formed from tributaries that originate around the lobar and segmental bronchi and from branches from the pleura in the neighborhood of the hilum. Bronchial venous blood empties into the azygos, hemiazygos, or intercostal veins and flows into the right atrium. Veins that originate from bronchial capillaries within the lungs unite to form venous tributaries that join the pulmonary veins with these communicating vessels termed the “bronchopulmonary veins.” Blood leaving the capillary bed around terminal bronchioles flows through anastomoses with alveolar capillaries, and the mixture returns to the left atrium via pulmonary veins.

The distribution of bronchial arterial inflow between the two available venous outflow pathways is unknown in humans, with tentative conclusions drawn from the technically demanding studies in experimental animals. These indicate that approximately 25% to 33% of the bronchial arterial supply returns ultimately to the right atrium via bronchial veins, and 67% to 75% flows into the left atrium via pulmonary veins.²⁷

Controversy still exists concerning the presence and significance of *bronchopulmonary arterial anastomoses* (i.e., direct vascular connections between pulmonary arteries and bronchial arteries). Available evidence suggests that bronchopulmonary arterial anastomoses exist,²⁷ are readily identifiable in neonatal lungs but are infrequent in normal lungs, and increase considerably in certain lung pathologic conditions.^{29,30}

BLOOD-GAS INTERFACE

The pulmonary capillaries form an extensive network interwoven with a meshwork of parenchymatous connective tissue (fine collagen and elastin fibers)³¹ in the interalveolar *septa*, the walls that separate adjacent alveoli. The capillary bed has been described either as a hexagonal meshwork of cylinders only minimally longer than its diameter, or as a sheet with the two sides periodically connected by septal tissue posts.³² These two models are useful for theoretical analysis of flow in pulmonary capillaries, but each represents simplification of a complex capillary network. Capillary perfusion begins when intracapillary pressure begins to exceed alveolar pressure and additional capillaries are

recruited, with further increases in capillary pressure depending on the tension in the alveolar wall, whether imposed by positive airway pressure or by gravity when the lung is suspended in an intact thorax.³³

Pulmonary capillaries, composed of capillary endothelium contiguously arranged to form a thin vascular tube, weave through the interstitial space of the interalveolar septum, facing first one alveolus and then another, thereby crossing several alveoli. Both the endothelium and the neighboring type I and type II alveolar epithelium rest on individual basement membranes, which appear to be fused over more than 50% of the capillary perimeter, thereby forming the *thin portion* of the alveolar-capillary septum. This is an ideal site for gas exchange because of the maximum surface area available for gas exchange combined with an extremely short diffusion distance. The thin septum consists of connective tissue elements (primarily collagens I and IV) that provide structural support.³⁴ In the remaining half of the capillary perimeter, the endothelial and epithelial basement membranes are separated to form an interstitial space (i.e., the *thick portion* of the alveolar septum, which represents the primary site of transcapillary fluid and solute exchange and consists of a variety of collagen fibers, elastin, and proteoglycans).³⁴ The existing barriers from the air space to the vessel lumen are the *alveolar epithelium*, *basement membranes* of the epithelium and endothelium, the *interstitial space* that exists within the thick septum but not the thin septum, and the *endothelium*.

IMAGING THE PULMONARY CIRCULATION

Advances in techniques to image the pulmonary circulation in recent years serve as invaluable tools to evaluate patients with potential pulmonary vascular abnormalities or diseases. Although *computed tomography* is one useful modality for these purposes, *magnetic resonance imaging* (MRI) is recognized as the most effective approach currently in use by virtue of its ability to visualize vessels regardless of orientation and to provide functional in addition to anatomic information.^{35,36} In addition, MRI, unlike computed tomography, does not require administration of potentially toxic radiation or contrast agents.

Two MRI techniques of high utility are contrast-enhanced *magnetic resonance angiography* and *phase-contrast magnetic resonance velocity mapping*. Magnetic resonance angiography relies on the intravenous administration of gadolinium to obtain rapid and detailed imaging of lung vascular anatomy with a total imaging time of less than 20 seconds,³⁷ often acquiring relatively high resolution three-dimensional images within 3 to 4 seconds. This allows for pulmonary vasculature visualization even in significantly dyspneic patients unable to hold their breath for a prolonged period of time.^{38,39} Relying on a pixel-by-pixel analysis of signal intensity-time course curves, magnetic resonance angiography is also capable of providing functional data, including quantitation of regional perfusion in terms of flow, mean transit time, and volume throughout the lungs.³⁹ Alternatively, phase-contrast MRI provides similar functional assessments derived from measurements of phase shifts of moving nuclei relative to stationary nuclei.⁴⁰ Although precise measurements can most reliably be obtained from the central vessels using this technique, flow patterns can be accurately determined throughout the lung vasculature, including the peripheral veins, and, in general, phase-contrast MRI flow measurements provide greater than 95% accuracy.^{41,42}

MRI of the pulmonary circulation offers significant clinical applications. For example, MRI provides full visualization of anomalous pulmonary venous connections (representing approximately 2% of congenital heart diseases)⁴³ and assessment of hemodynamic parameters. Thoracic MRI has improved its potential in pulmonary thromboembolism,⁴⁴ whereas use of multidetector-row CT has been used in quantifying bilateral bronchial narrowing.⁴⁵ Separately, magnetic resonance angiography is now the optimal modality to evaluate pulmonary vein stenosis, surpassing the sensitivity of echocardiography³⁷ and allowing assessment of stenotic lesions in addition to the collateral circulation. A number of other potential clinical applications with respect to the pulmonary vasculature have shown high promise and continue to be the focus of investigation, including the evaluation of patients with chronic thromboembolic disease,⁴⁶ arteriovenous malformations,^{47,48} and pulmonary vasculitis.⁴⁹

Figure 6-1 Method of determining pulmonary wedge pressure. By placing a catheter through the right heart and pulmonary artery (PA) and occluding a small PA with a balloon, the static fluid column within the catheter is functionally extended from the catheter tip through the capillaries and into pulmonary veins (PVs). The pressure measured is at the confluence of veins, where flow is again present. Because the pressure drop from a large vein to the left atrium (LA) is small, wedge pressure is a reflection of left atrial pressure except when (1) there is a change in downstream resistance, indicated by constriction (solid semicircles) proximal to the LA or (2) the catheter is in an artery perfusing a capillary bed where alveolar pressure exceeds PV pressure (i.e., zone 1 or 2). In the latter case, when the balloon is inflated, pressure within the capillary bed falls toward PV pressure, capillaries are compressed, the fluid column is interrupted, and wedge pressure will no longer reflect left atrial pressure (see Fig. 6-2).

decreases across the pulmonary circuit, the pulsatile nature of the flow persists on the venous side.⁵⁰ *Pulmonary artery pressure* (PPA) is normally approximately 25 mm Hg during systole and 9 mm Hg during diastole. Relative to systemic arterial pressure, PPA is low, and hydrostatic pressure differences due to gravity result in a substantial difference in vascular pressure from the top to the bottom of the lung. If the pulmonary artery is considered to be a column of blood approximately 25 cm high, there will be a 25 cm H₂O (or 18 mm Hg) PPA increase from the bottom to the top of the lung (1 mm Hg pressure = 1.36 cm H₂O pressure). This pressure difference results in a nonuniform distribution of blood flow, as discussed subsequently in the “Regional Distribution of Pulmonary Perfusion” section.

PPA is measured by inserting a cardiac catheter or a balloon-tipped flotation catheter into the pulmonary artery.⁵¹ Inflating the balloon leads to advancement (“floating”) of the catheter (Fig. 6-1) until it “wedges” and occludes a peripheral pulmonary artery. With the balloon inflated the pressure measured in the tip of the catheter is called the *pulmonary wedge pressure* (PPW).^{52,53} This procedure effectively extends the static fluid within the catheter lumen into the vascular bed, and the measured pressure is thus at the site where this extended column next joins a vessel in which blood is flowing. The wedge pressure (normally 5 to 10 mm Hg) is an estimate of the vascular pressure at the point of confluence of pulmonary veins and hence reflects *left atrial pressure* (PLA).

Changes in pressure distal to the confluence of the pulmonary veins, such as that induced by constriction of the pulmonary venules, can alter the relationship between PLA and PPW. Also, the precise location of the catheter tip in the lung influences the measurement of PPW (Fig. 6-2). Zone 1 is the region of the lung in which the *alveolar pressure* (Palv) is greater than PPA, which is greater than the *pulmonary venous pressure* (PPV), and therefore there is minimal blood flow through the alveolar vessels. Zone 2 is where PPA is greater than Palv, which is greater than PPV, and therefore flow increases linearly as one moves down the lung. Positioning the catheter in the upper lung (in zone 1 or 2)

Figure 6-2 Illustration of the influence of catheter position on wedge pressure measurement over time. When the catheter is wedged in a *low* position (i.e., zone 3), wedge pressure (PPW-Lo) reflects left atrial pressure (PLA) (see at 10 minutes). When the catheter is wedged in a *high* position (PPW-Hi), however, the pressure does not reflect PLA because, when the catheter is wedged, pulmonary venous pressure is less than alveolar pressure (i.e., zone 2), the capillary bed is compressed, and the catheter measures alveolar pressure. With a saline infusion, pulmonary venous pressure rises, capillaries open (i.e., zone 3), and PPW-Hi now measures pulmonary venous pressure, becoming equal to PLA. With hemorrhage, pulmonary venous pressure falls again, and PPW-Hi again becomes greater than PLA. (From Todd TR, Baile EM, Hogg JC: Pulmonary arterial wedge pressure in hemorrhagic shock. *Am Rev Respir Dis* 118:613–616, 1978.)

results in a PPW different from PLA because higher alveolar pressures occlude the fluid column. Under these conditions, PPW provides an incorrect measurement of pulmonary vascular outflow pressure. A catheter wedged in zone 3, where PPA is greater than PPV, which is greater than Palv, more accurately reflects the PLA.^{54,55} Various algorithms have been proposed to validate measurements of PPW.⁵⁵

PULMONARY VASCULAR RESISTANCE

Pulmonary vascular resistance (PVR) is calculated by the following equation:

$$PVR = \frac{PPA - PLA}{\dot{Q}_T} \quad (1)$$

where \dot{Q}_T is cardiac output, PPA is mean pulmonary artery (inflow) pressure, and PLA is mean left atrial (outflow) pressure, which is often estimated by PPW. PVR is expressed in units of mm Hg/L/min or in dyne·sec·cm⁻⁵ (to convert units to dyne·sec·cm⁻⁵, PVR in mm Hg/L/min is multiplied by 1332). The normal PVR value is approximately 0.1 mm Hg/L/min, or 100 dyne·sec·cm⁻⁵. This value is approximately one tenth the value of systemic vascular resistance.

The use of Equation 1 (from Ohm's law) is complicated by the fact that resistance is not independent of PPA or PLA. As an example, if both PPA and PLA were elevated to such a degree that the pressure difference remained unchanged, PVR would nevertheless decrease because of distention of vessels by higher intravascular pressures. Thus inferences regarding resistance changes in the vasculature require

consideration of multiple mechanical factors that affect vascular resistance, including not only vascular pressures but also lung volume and inflation pressure. PVR is a function of lung volume because inflation distends some vessels and compresses others, as described later in the discussion of alveolar and extra-alveolar vessels.

PVR can also be potentially modeled by Poiseuille's law, which, for laminar flow, describes the relationship of resistance (R) of a tube to the tube's physical characteristics and viscosity of perfusing fluid:

$$R = \frac{8}{\pi} \cdot \frac{l}{r^4} \cdot \eta \quad (2)$$

where l is the length of the tube, r is the radius of the tube, and η is the viscosity of the perfusion fluid. It is evident from this equation that the critical factor determining PVR is the change in the tube's radius because resistance is proportional to $1/r^4$. Although this suggests that a 50% decrease in the tube radius, potentially encountered with vessel constriction, increases resistance 16-fold, this derived relationship may be excessively robust. Ohm's law and Poiseuille's law, although useful in describing the resistance properties of pulmonary vessels, have limitations that must be considered when changes in the calculated PVR value are interpreted. Characteristics unaccounted for in either equation include the following: blood flow is pulsatile, blood vessels are complex distensible branching tubes (not rigid cylinders), and blood-formed elements in the plasma constitute a nonhomogeneous fluid. Nevertheless, the ratio of pulmonary perfusion pressure to blood flow under strictly controlled conditions is a useful measure of pulmonary vasomotor tone with the caveat that its usefulness depends on knowledge of levels of intravascular pressure, pulmonary blood volume, and lung volume. Recent estimations of PVR using the ratio of pulmonary artery systolic pressure to the right ventricular outflow tract velocity time integral may provide a superior assessment of PVR.⁵⁶

Vascular Resistance Profile

The vascular resistance profile in the pulmonary circuit has been estimated by micropuncture studies.^{57,58} In zone 3 conditions, where vascular resistance is not influenced by alveolar pressure, the majority of the resistance lies in pulmonary microvessels with nearly 50% of total resistance residing in alveolar capillaries (Fig. 6-3). These results indicate that the small pulmonary arteries and capillaries account for most of the pressure drop across the pulmonary vascular bed, a finding in striking contrast to the systemic circulation, where the arterioles account for the greatest pressure drop.

Mechanical Effects on Pulmonary Vascular Resistance

Transmural Pressure. The importance of transmural pressure is highlighted by the experiments described in Figure 6-4 where, at a constant PLA, increases in PPA caused a decrease in PVR; however, as PLA was raised, increases in PPA had progressively less effect.^{59,60} This indicates that the vessels are nearly maximally dilated at high levels of PLA and that, after a certain PLA is reached, additional increases in transmural pressure (produced by elevating PPA) do not produce further decreases in PVR.

Figure 6-3 Distribution of vascular resistance as determined by micropuncture measurement of pressures. Unlike the situation in the systemic circulation, the majority of the vascular resistance in the pulmonary circuit resides in the capillaries. Measurements were made in subpleural vessels of isolated dog lungs under zone 3 conditions. PA, pulmonary artery; PV, pulmonary vein. (From Bhattacharya J, Staub NC: Direct measurement of microvascular pressures in isolated perfused dog lung. *Science* 210:327–328, 1980.)

Figure 6-4 Pulmonary vascular resistance is dependent upon the pulmonary arterial pressure. As pulmonary arterial pressure increases, vessels are distended and resistance falls. This effect is diminished at higher left atrial pressures (PLA) because the vascular bed is already near maximal distention. (Data from Borst HG, McGregor M, Whittenberger JL, Berglund E: Influence of pulmonary arterial and left atrial pressures on pulmonary vascular resistance. *Circ Res* 4:393–399, 1956.)

Lung Volume. Changes in lung volume produce opposite effects on the caliber and the resistance of alveolar and extra-alveolar vessels (Fig. 6-5). For alveolar vessels, the perivascular pressure is generally slightly lower than alveolar pressure as a result of the elastic recoil of alveolar walls, reflecting both surface tension created by the layer of liquid at the air-liquid interface⁶¹ and traction on membranes surrounding the interstitial space produced by alveolar wall attachments.⁶² In effect, surface tension forces tend to collapse alveoli, thereby decreasing perivascular

Figure 6-5 Pulmonary vascular resistance increases as lung volume is decreased from functional residual capacity (FRC) to residual volume (RV) because of the influence of rising interstitial pressure on extra-alveolar vessels. Resistance also increases with lung inflation from FRC to total lung capacity (TLC) because of stretched and flattened alveolar vessels. (From Murray JF: *The normal lung*, ed 2, Philadelphia, 1986, WB Saunders.)

pressure relative to alveolar pressure. However, during lung inflation, alveolar vessels are compressed and elongated.⁶³ Therefore, as the lung increases from residual volume to total lung capacity, resistance of alveolar vessels progressively increases.

In contrast, extra-alveolar vessels are subjected to different stresses. When interstitial pressure surrounding extra-alveolar vessels decreases with lung inflation, the resulting increased transmural pressure causes a decrease in resistance of these vessels. Corner vessels are also subjected to this same decreasing interstitial pressure and also show a decreased resistance with lung inflation. Thus, with lung inflation, the resistance of extra-alveolar vessels progressively decreases (see Fig. 6-5).

Because the resistances of alveolar and extra-alveolar vessels are in series, the resistances are additive and the change in PVR forms a “U”-shaped curve, with the nadir of the curve operating at approximately functional residual capacity, the usual end-expiratory lung volume. Any increase in the perivascular pressure of alveolar vessels or extra-alveolar vessels increases the resistance of these vessels. For example, tissue edema is associated with an increase in the interstitial fluid pressure,⁶⁴ which decreases the transmural pressure and thereby leads to the increase in PVR associated with pulmonary edema. Severe alveolar edema serves to compress alveolar vessels and can contribute to the increased PVR associated with alveolar flooding.

Viscosity. The viscosity term (η) of Poiseuille’s law (Equation 2) predicts that an increase in blood viscosity produces a proportional increase in the PVR. Viscosity is a function of the deformability of red blood cells in pulmonary microvessels, the viscosity of plasma⁶⁵ with the hematocrit being the primary factor determining viscosity of the blood.⁶⁶ Figure 6-6 shows the effects of changes in the hematocrit on pulmonary arterial pressure at three levels

Figure 6-6 Effect of hematocrit on pulmonary artery pressure at three levels of blood flow (0.5, 1.5, and 2.5 L/min are depicted). Left atrial pressure (PLA) was held constant at 3.5 mm Hg. As the hematocrit (Hct) is increased at constant levels of pulmonary flow, pulmonary artery pressure increases, reflecting the higher vascular resistance caused by increased blood viscosity. With an increase in Hct above 40%, the pressure and resistance rise rapidly. (From Murray JF, Karp RB, Nadel JA: Viscosity effects on pressure-flow relations and vascular resistance in dogs’ lungs. *J Appl Physiol* 27:336–341, 1969.)

of blood flow. At each level of blood flow, it is evident that blood hematocrit values greater than 40% produce rapid increases in PPA and PVR. Although controversial, hypoxia-induced polycythemia and the resulting increased viscosity appear to be major factors contributing to the increased PVR at high altitude.⁶⁷

PULMONARY VASCULAR COMPLIANCE

Pulmonary Vascular Pressure-Volume Curve

The pulmonary vasculature is a highly compliant circuit¹³ with the pulmonary blood volume normally constituting approximately 10% of total blood volume. The distribution of blood volume among the arterial, capillary, and venous volumes is, however, highly dependent on the technique of measurement and on whether arteries, capillaries, and veins are defined functionally or anatomically. Human capillary blood volume has been functionally estimated⁶⁸ to be approximately 75 mL or approximately 10% to 20% of total pulmonary blood volume. However, estimates in animals have generally shown a higher proportion of pulmonary blood volume within the capillaries.^{34,51}

The pressure-volume curve of the pulmonary vasculature is linear at low levels of pulmonary perfusion pressure, where small changes in volume result in small changes in pressure, and becomes nonlinear at higher pressures, where small changes in volume cause large changes in pressure. Pulmonary vascular compliance is defined as $\Delta V / \Delta P$, where ΔV is the change in pulmonary vascular volume and ΔP is

the change in transmural pressure. Microvessels^{69,70} are usually the primary site of vascular compliance, although others have postulated that larger pulmonary vessels may also contribute to vascular compliance.⁷¹

Changes in Vascular Compliance

Pulmonary vascular compliance decreases with increases in sympathetic nerve activity.⁷² The pulmonary circulation thus serves as a vascular reservoir that responds to sympathetic stimulation by increasing left atrial filling pressure and increasing cardiac output. Pulmonary vascular compliance is also influenced by changes in lung volume secondary to alterations in intrapleural pressure. Because a substantial fraction of blood volume is localized in large pulmonary arteries and veins (largely extra-alveolar vessels), lung inflation increases transmural pressure, passively enlarges these vessels, and thereby increases blood volume within the pulmonary circuit. In contrast, reductions in lung volume reduce pulmonary blood volume within the pulmonary circuit.⁷³

PULMONARY PERFUSION

Distention and Recruitment

Pulmonary microvessels can either be recruited (i.e., new vessels “brought into play” in the microcirculation) or be distended (i.e., already perfused vessels dilating as a result of increased transmural pressure). It is not always clear which process predominates in response to increasing pulmonary capillary pressures.⁵⁰ It is likely that there are regional differences in the relative importance of recruitment and distention of pulmonary vessels. In zone 1, alveolar vessels are more likely to be recruited when transmural pressure rises, because vessels are normally collapsed in this region.⁷⁴ In zone 2, both recruitment and distention are likely, due to the uneven perfusion in this region.^{74,75} In zone 3, distention is likely to predominate, because this lung region is more consistently perfused than other regions.⁷⁴

Regional Distribution of Pulmonary Perfusion

Because of gravity, mean intravascular pressures are lowest at the apex of the lung and highest at the base. Therefore, because alveolar pressure is constant throughout the lung, pulmonary blood flow is a function of its vertical height; blood flow is dependent upon the interactions among mean PPA, mean PPV, and Palv.

In zone 1, the uppermost region, blood flow is limited and alveolar vessels are collapsed because Palv is greater than PPA and PPV.^{74,76-78} Flow in zone 1 persists to a limited degree because pericapillary pressures in zone 1 are slightly lower than Palv because of the surface tension of the alveolar lining layer⁷⁹ and because corner vessels are not subject to changes in Palv.⁵⁹ A final factor contributing to continuing zone 1 perfusion is the pulsatile nature of pulmonary capillary pressure, which recruits capillaries with intermittent bursts of flow during systole.⁸⁰

In zone 2, where PPA is greater than Palv, which is greater than PPV, blood flow begins just below the level of lung where PPA equals Palv; moving linearly downward, PPA progressively increases in relation to Palv, and blood flow steadily increases. Pulmonary perfusion in zone 2 is deter-

mined by the pulmonary arterial minus *alveolar* pressure difference, or $PPA - Palv$, rather than the arterial minus *venous* pressure difference, the gradient that normally governs blood flow in most vascular beds. Zone 2 conditions have been compared to a “vascular waterfall” or “sluice,” because perfusion is independent of PPV, the downstream pressure.

In Zone 3, a more dependent region of the lung, PPA is greater than PPV, which is greater than Palv and results in a more gradual increase in flow because the increasing intravascular pressures progressively dilate the vessels, thereby lowering regional vascular resistance and causing blood flow to increase steadily. This region is the major site of gas exchange because it receives the preponderance of blood flow and of ventilation.⁷⁶⁻⁷⁸

Zone 4 is the region in the most dependent portion of the lung in which blood flow decreases from the peak observed in zone 3. This zone is a reflection of conditions at the base of the lung, where alveoli may be poorly ventilated or even nonventilated because airways leading to the region are narrowed or closed, producing local alveolar hypoxia, arterial vasoconstriction, and an increase in PVR. In addition, at low lung volumes, extra-alveolar vessels become compressed because interstitial pressure increases, causing PVR to rise.⁷⁸ Moreover, pathologic conditions that lead to perivascular edema may be associated with the development or enlargement of zone 4.⁸¹

Because of the prevailing intravascular pressures, zone 1 does not exist in the lungs of healthy humans under ordinary conditions, even when upright. The majority of the normal lung functions in zone 3 and only the uppermost region in zone 2. Decreases in intravascular pressures (hemorrhagic shock or positive end-expiratory pressure-induced increase in intra-alveolar pressure) expands zone 2 and possibly creates zone 1 conditions. Increased resolution in blood flow measurements has resulted in proposed modifications of the zone gravity model⁸² with incorporation of newer concepts of fractal vascular trees and perfusion heterogeneity, together suggesting that the pulmonary vascular structure is an additional critical factor in determining regional blood flow.^{82,83}

Additional in-depth reviews of hemodynamic aspects of the pulmonary circulation should be consulted for supplementary material and perspectives.^{50,51,84,85} The effect of gravity on blood flow and the implications of this effect in terms of gas exchange are also discussed in Chapter 4.

MECHANICAL STRESS AND THE LUNG CIRCULATION

Lung inflation and the pulsatile nature of blood pressure and flow exposes blood vessels to hemodynamic forces in the form of shear stress and cyclic stretch. The endothelium converts these mechanical stimuli to intracellular signals that affect cellular functions, including proliferation, migration, remodeling, permeability, and apoptosis. The cytoskeleton is the key structural framework for endothelial cells to transmit mechanical forces from its luminal, abluminal, and junctional surfaces to its interior. Changes in vascular mechanical stress activate multiple sensing mechanisms and signaling networks resulting in physiologic and pathologic functional responses.

Shear Stress

The flow of blood parallel to the vessel surface produces fluid shear stress from the friction of blood against the vessel wall. Endothelial cells are the primary vascular cells exposed to shear stress from laminar blood flow. The response of endothelial cells to physiologic levels of shear stress serves a number of regulatory functions including (1) vascular remodeling, (2) modulation of hemostasis and thrombosis, (3) modulation of inflammation through the expression of chemotactic and adhesion molecules on membrane surfaces, and (4) vascular smooth muscle cell contraction through the release of vasodilators and vasoconstrictors.⁸⁶ Endothelial cell perfusion at the physiologic shear stress of 10 dynes/cm² has been associated with vascular barrier enhancement (Fig. 6-7), suggesting that shear stress is important in normal vascular barrier maintenance.⁸⁷ In the systemic circulation, disruption or unsteady blood flow at atherosclerosis-prone regions of blood vessels can impair these functions, leading to proatherogenic and/or prothrombotic states. Endothelial cells use multiple sensors for shear stress, including membrane receptors such as integrins,^{88,89} vascular endothelial growth factor receptor-2,⁸⁹ ion channels,⁹⁰ platelet endothelial cell adhesion molecule-1, and components of the endothelial glycocalyx.^{91,92} These sensors can interact with each other and transactivate multiple signaling pathways,^{93,94} including p38 and p42/44 mitogen-activated protein kinase,^{95,96} and tyrosine kinases

such as c-Abl⁹⁷ and focal adhesion kinase.⁹⁸ These signals lead to altered gene expression^{86,99} and rapid cytoskeletal rearrangement evidenced by flow-directed reorientation of the endothelium.^{100,101} Shear stress-mediated production of *reactive oxygen species* (ROS) via nicotinamide adenine dinucleotide phosphate, reduced form activation regulates normal cell growth, proliferation, and differentiation.^{102,103} ROS signaling in settings of chronic inflammation, however, exacerbates smooth muscle contractility and vascular remodeling associated with pulmonary hypertension, acute lung injury, or pulmonary edema.¹⁰⁴ Shear stress also serves a protective role by reducing endothelial cell turnover through inhibition of cell proliferation and suppression of apoptosis via activation of the PI3K-AKT survival pathway and nitric oxide production.¹⁰⁵⁻¹⁰⁷ The variability of vessel properties along with the pulsatile nature of blood flow results in temporal and spatial variations of shear stress on the vessel wall. In the straight part of the vessel, blood flow is undisturbed with a mean shear stress of 10 to 70 dynes/cm².¹⁰⁸ However, blood flow patterns in the bends and bifurcations are disturbed, leading to eddies in which peak shear stresses can exceed 100 dynes/cm².^{109,110}

Cyclic Stretch

Cyclic stretch is also an important mechanical force generated in the lung circulation by either circulating blood (which produces pulsatile distention of the arterial wall) or by tidal breathing. Blood pressure represents the major

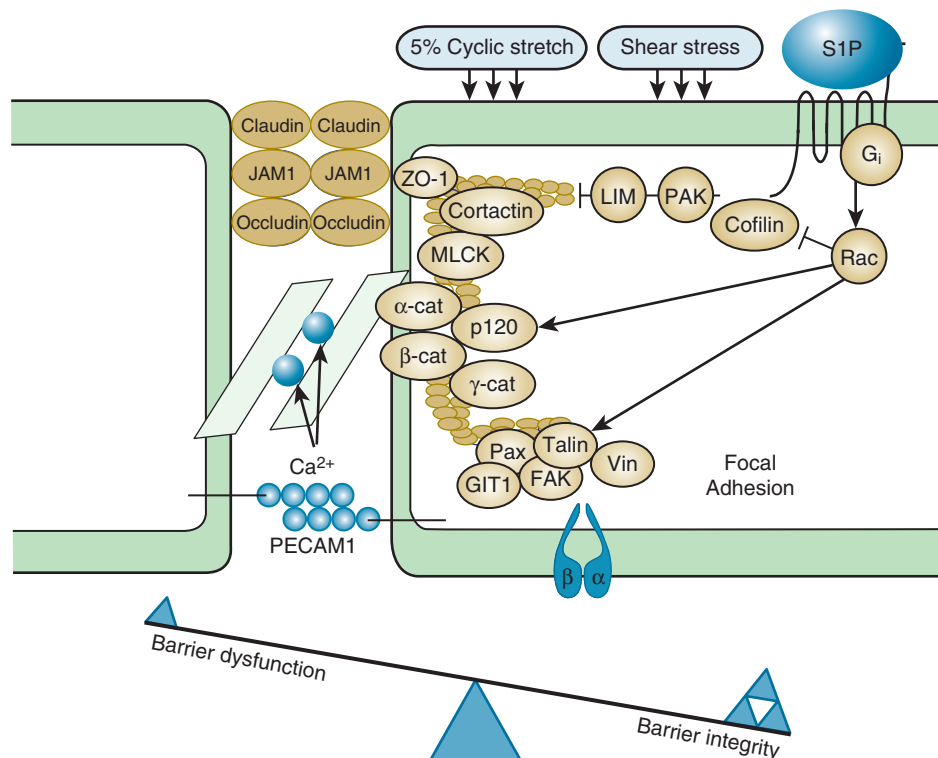

Figure 6-7 Schematic depicting enhanced endothelial cell barrier function by sphingosine-1-phosphate. Sphingosine-1-phosphate (S1P), an angiogenic growth factor, activates specific G protein-coupled S1P receptors, leading to profound cytoskeletal rearrangement and increased barrier function in vitro and in vivo.^{261,331,336,337} Ligand of S1PR1 results in activation of Rac GTPase, a signaling cascade that results in cytoskeletal rearrangement and increased cortical actin with increased linkage to the adherens junction and focal adhesions. Rac activation initiates intracellular events dependent on specific protein kinase C isotypes, p21-associated kinase (PAK), LIM-kinase, the actin-severing protein cofilin, and myosin light chain kinase (MLCK), which all contribute to increased cell-cell and cell-matrix tethering. cat, catenin; Gi, inhibitory G protein; FAK, focal adhesion kinase; GIT1, G protein-coupled receptor kinase interacting protein 1; Pax, paxillin; PECAM1, platelet-endothelial cell adhesion molecule-1; Vin, vinculin.

determinant of vessel stretch.^{111,112} Similar to shear stress, cyclic stretch induces reorientation of the endothelium in a transverse direction.^{111,113,114} In vitro endothelial cell exposure to 5% cyclic stretch (a physiologic level of mechanical stress) results in rapid Rac GTPase-mediated signaling¹¹⁵ and redistribution of actin¹¹¹ and cortactin,^{87,115} an actin-binding protein, toward the cell periphery (see Fig. 6-7). Furthermore, in comparison to static conditions, physiologic stretch induces desensitization to edemagenic agents, as evidenced by the reduction of thrombin-induced paracellular gap formation.^{111,115} In contrast, endothelial exposure to 18% cyclic stretch, a pathologic level of excessive distention mimicking high tidal volume mechanical ventilation, induces Rho GTPase activation¹¹⁴ and increased sensitivity to edemagenic agonists (Fig. 6-8). This is reflected by increased vascular leak^{111,114} via increased signaling and expression of contractile proteins including Rho GTPase, myosin light chains, myosin light chain kinase, PAR1, caldesmon, and HSP27, suggesting regulation at both the translational and posttranslational level.^{111,116} Sustained in vitro or in vivo exposure to excessive cyclic stretch also increases microparticle shedding from the endothelial surface and provides yet another pathway of sustained

inflammation. Clinically, lung overdistention caused by mechanical ventilation at high tidal volumes induces remodeling of the extracellular matrix.¹¹⁷ Cellular responses to mechanical stress include increased inflammatory cytokine production, macrophage activation, acute inflammation, and barrier dysfunction resulting in pulmonary edema. Reductions in tidal volume serve to decrease mechanical stress and extracellular matrix disorganization,¹¹⁷ resulting in improved patient mortality from ventilator-induced lung injury.^{118,119} Chronic exposure of the pulmonary circulation to increased cyclic stretch induces vascular cell proliferation, collagen and fibronectin synthesis, and alveolar and vascular remodeling.^{120,121}

PULMONARY VASCULAR RESPONSES TO HYPOXIA

Response Elements

Alveolar hypoxia, defined as an alveolar PO_2 of less than 70 mm Hg, typically elicits pulmonary vasoconstriction.¹²² Isolated lung experiments have shown that the most important stimulus for vasoconstriction is hypoxia at the alveolus,

Figure 6-8 Schematic depicting the disruption of endothelial cell barrier homeostasis by thrombin. In this working model of lung vascular barrier regulation, a balance exists under basal conditions between actomyosin contractile and cellular adhesive forces. Thrombin cleavage of the PAR1 receptor on the surface of the endothelial cell results in activation of contractile forces via both heterotrimeric G proteins (G_q , $G_{12/13}$) and small GTPases such as Rho. Activated Rho (Rho-GTP) induces increased Rho kinase (Rho K) activity and phosphorylation of the phosphatase regulatory subunit thereby inhibiting the myosin phosphatase (MYPT). Rho K and myosin light chain kinase (MLCK) are activated via independent pathways. Increased cytosolic calcium (via inositol triphosphate production) activates the calcium/calmodulin-dependent MLCK, with conformational changes allowing the enzyme to access the preferred substrate, myosin light chain (MLC). Rho K and MLCK activation both culminate in increased MLC phosphorylation, which in turn enables actomyosin contraction resulting in increased stress fiber formation, cellular contraction, paracellular gap formation, and ultimately barrier dysfunction. Increases in cyclic adenosine monophosphate (cAMP) influence both calcium mobilization and MLCK activity. Additional regulatory proteins, such as heat shock protein (HSP27) and the actin capping/severing proteins, cofilin and gelsolin, are also involved in stress fiber rearrangement. PLC, phospholipase C.

as opposed to hypoxemia of pulmonary arterial blood.⁵¹ Vasoconstriction mainly involves the small precapillary vessels.¹²³⁻¹²⁵ The vasoconstrictor response to hypoxia is unique to pulmonary vessels; exposure of systemic vessels to hypoxia results in vasodilation. The hypoxic pulmonary vasoconstrictor response serves a regulatory function in matching perfusion to ventilation by shunting perfusion away from poorly oxygenated regions of the lung. Alveolar hypoxia in a lung segment causes significant diversion of blood flow to the more normoxic regions of the lung.¹²⁶

Neurohumoral signals generated during hypoxia have been invoked to explain the response, but the basis of the constriction still remains unknown.¹²⁷ Because the hypoxic pulmonary vasoconstrictor response is retained in isolated-perfused lungs and in isolated small (<300 μ m) pulmonary arteries,¹²⁸ it is unlikely that it is the result of nerve stimulation. However, local activation of peptidergic nerves and axon reflexes cannot be discounted. No study to date has identified a blood-borne or released mediator that accounts for the hypoxic vasoconstriction response, although several candidates identified by genomic strategies have been suggested.¹²⁹ Several bioactive mediators potentially modulate the magnitude of the hypoxic response by influencing the basal pulmonary vasomotor tone. The extent of the response to hypoxia is species dependent and correlates with the amount of smooth muscle present in pulmonary arteries.¹³⁰ Calves with an abundant amount of pulmonary vascular smooth muscle, such as those born at high altitude, have a pulmonary vascular bed that is highly reactive to hypoxia.¹³¹ In humans, nitroglycerin or *nitric oxide* (NO) attenuate hypoxic pulmonary vasoconstriction and, by disrupting the matching of ventilation to perfusion, can produce hypoxemia.¹³²

Chronic exposure to hypoxia increases the muscular content of small arteries that are normally devoid of smooth muscle.¹⁰ People native to high altitude in the Andes have an increased muscularization of arteries as small as 20 μ m.¹³³ However, not all high-altitude natives¹³⁴ nor all animals living at high altitudes exhibit this response.¹¹ This suggests that genetic factors exist that regulate the pulmonary vascular remodeling seen during hypoxia.^{135,136}

The hypoxic pulmonary vasoconstrictor response is augmented by increases in plasma hydrogen ion concentration.¹³⁷ The partial pressure of carbon dioxide acts only via its effect on pH.^{138,139} The increased hydrogen ion concentration in pulmonary vascular smooth muscle cells resulting from hypoxia or carbon dioxide is an important intracellular signal mediating the interaction between actin and myosin filaments and thus vascular tone.

The hypoxic pulmonary vasoconstrictor response is also affected indirectly by a variety of mediators. The vasoconstrictor response is augmented by cyclooxygenase inhibitors¹⁴⁰ via prevention of prostacyclin generation. An increase in left atrial pressure and in blood volume can prevent the hypoxia-induced pulmonary vasoconstriction, which indicates that transmural pressure changes influence the response.¹⁴¹ Another significant factor potentially influencing the hypoxic pulmonary vasoconstrictor response is NO. As shown in pulmonary artery ring studies, acetylcholine-mediated vasodilation depends upon an intact endothelium that releases NO.^{142,143} Antagonists of

endothelium-dependent relaxation potentiate hypoxic pulmonary vasoconstriction.¹⁴⁴ Pulmonary vascular endothelial cells activated by hypoxia may not release NO to the same extent as systemic vessels. In addition to NO, there are other endothelium-derived relaxing factors. For example, endothelium-derived hyperpolarizing factor is the likely mediator of endothelium-derived relaxation that cannot be attributed to NO.¹⁴⁵ Endothelium-derived hyperpolarizing factor mediates its vasodilator effect by causing the calcium-dependent potassium channels to open, leading to hyperpolarization.¹⁴⁶ However, the role of endothelium-derived hyperpolarizing factor in the control of basal and hypoxic pulmonary vasoconstriction is not known. The bioactive peptide, endothelin, is a constricting factor released by systemic and pulmonary endothelial cells by hypoxia. However, these experiments were made with arteries larger than those generally considered to be responsible for hypoxic pulmonary vasoconstriction.

In addition to these indirect effects on vasoconstriction, there may be direct effects of hypoxia on the vascular smooth muscle cells. Hypoxia may be sensed via the proximal mitochondria electron transport chain, which decreases ROS production in response to hypoxia. This event results in a decrease in superoxide or hydrogen peroxide and inhibition of the potassium channel that elicits membrane depolarization.¹⁴⁷⁻¹⁴⁹ This results in the opening of a calcium channel and an influx of calcium that mediates pulmonary arterial smooth muscle contraction.¹⁴⁷⁻¹⁴⁹ Because metabolic inhibitors enhance hypoxic vasoconstriction, a hypoxia-induced decrease in oxidative phosphorylation has also been suggested as a possible mechanism.¹⁵⁰ Evidence of energy failure has not been found except at such low oxygen levels that vessels actually dilate rather than constrict.¹⁵¹ However, it is likely that changes in oxidative phosphorylation may be a sensing and signal transduction mechanism that activates the inhibition of potassium channels.¹⁵⁰

Once stimulated, vasoconstriction is mediated by an increase in intracellular calcium ion concentration in smooth muscle cells, the "Ca²⁺ hypothesis."¹⁵² The increased intracellular calcium ion combines with the calcium-binding protein calmodulin to activate the enzyme *myosin light chain kinase* (MLCK), resulting in contraction. Calcium channel blockers inhibit and calcium channel agonists enhance^{153,154} the hypoxia-induced constriction of pulmonary vessels. At the same time, hypoxia augments RhoA and Rho kinase-mediated calcium ion sensitization. The increased RhoA and Rho kinase activity leads to dephosphorylation of myosin light chain phosphatase and increased myosin light chain phosphorylation leading to contraction.¹⁵⁵ The importance of Rho kinase signaling in this context is suggested by the attenuation of hypoxia-induced pulmonary vasoconstriction in mice treated with a Rho kinase inhibitor.¹⁵⁶ Calcium influx may result from membrane depolarization induced by hypoxia,¹²⁸ with resulting increased calcium permeability, release of intracellular stores of calcium, or both. However, it is not clear how hypoxia causes depolarization of the pulmonary vascular smooth muscle membrane or whether this leads to the influx of calcium via voltage-gated channels responsible for activating pulmonary vascular smooth muscle contractility.¹⁵⁷

Intermittent hypoxia is a clinically relevant problem in many patients, including those with obstructive sleep apnea or with chronic obstructive pulmonary disease. Animal models confirm that the physiologic consequences of intermittent hypoxia may be evident even after exceedingly brief but repeated exposures to low oxygen levels. For example, mice and rats subjected to intermittent 6% to 10% oxygen (30-second to 2-minute duration) for 8 hr/day over 4 to 5 weeks demonstrate significant increases in both right ventricular systolic pressure and right ventricular mass index,^{158,159} a significant increase in the number of muscular arterioles,¹⁵⁶ and significantly increased pulmonary artery pressures.¹⁵⁹ Although humans subjected to intermittent hypoxia may not manifest pulmonary hemodynamic changes to the same degree as observed in animal models,¹⁶⁰ efforts are ongoing to characterize pulmonary vascular responses to intermittent hypoxia.

NEURAL CONTROL OF PULMONARY VASCULAR RESISTANCE

Adrenergic and cholinergic efferent nerves are present in pulmonary arteries and veins in all mammals examined,¹⁹ although with considerable variation in both distribution and degree of innervation. Innervation of the pulmonary vasculature is typically less than that of the systemic arterial vessels. The concentration of fibers is greatest in large vessels and at branch points.¹⁶¹ α -Adrenergic receptors predominate in the pulmonary vascular bed,¹⁹ particularly in the fetal circulation, where there is high basal vasomotor tone and greater reactivity to α -adrenergic stimulation.¹⁶² Stimulation of α -adrenergic receptors mediates the constriction of pulmonary vessels, whereas β -adrenergic receptors mediate dilation.^{162,163} α -Adrenergic mechanisms contribute minimally to normal adult pulmonary vasomotor tone because antagonism of α -adrenergic receptors modifies neither baseline pulmonary vasomotor tone nor the response to hypoxia.¹⁶⁴ Because pulmonary vessels are normally in a dilated state, β -adrenergic responses are not evident. However, β -adrenergic blockade enhances the vasoconstrictor response to catecholamines, which stimulate both α - and β -receptors, and increases in tone augment responses to β -adrenergic agents.¹⁶⁵

There is limited understanding of the functional significance of sympathetic and parasympathetic innervation of pulmonary vessels. It is unclear why stimulation of these nerves produces relatively small changes in vasomotor tone in the adult lung. One possibility is that neural mechanisms balance the distribution of vascular resistance and compliance in the pulmonary vascular bed and thereby finely regulate regional and total pulmonary perfusion.⁵⁰ It is also possible that vasodilator influences (i.e., NO, endothelium-derived hyperpolarizing factor, and prostacyclin) normally predominate and thus mask the effect of nerve stimulation.

HUMORAL REGULATION OF PULMONARY VASCULAR RESISTANCE

Numerous pulmonary vasoconstrictor mediators (norepinephrine, angiotensin II, histamine, endothelin, serotonin, thromboxane, leukotrienes C₄ and D₄, platelet-activating

factor)^{50,84,166} bind to receptors on pulmonary vascular smooth muscle cells and induce pulmonary vascular smooth muscle contraction via second messenger pathways. Similar to the peripheral circulation, changes in pulmonary vasomotor tone induced by these constrictors are regulated by NO.¹⁶⁷

Various pulmonary vasodilator substances identified include acetylcholine (which mediates its effects in part by NO release) and bradykinin (which has heterogeneous responses with direct as well as NO-dependent actions), prostacyclin, and prostaglandin E₁.¹⁶⁷ It is important to note that the magnitude of the effects of both pulmonary vasoconstrictors and vasodilators is species dependent and influenced by baseline pulmonary vasomotor tone. The latter is particularly important because, depending on vasomotor tone, pulmonary vasoconstrictors such as platelet-activating factor can have dual effects: inducing constriction in the pulmonary vascular bed when it has low basal tone, but inducing dilation in the pulmonary vascular bed when it has increased tone. The basis for these divergent effects is unclear but may reflect differential activation of second messenger pathways in pulmonary vascular smooth muscle cells in the basal state compared to a state of increased tone.

The role of the renin-angiotensin system in pulmonary vascular regulation is now well recognized. Angiotensin II, a key component of the renin-angiotensin system, is generated primarily by *angiotensin converting enzyme* (ACE) from angiotensin I, and its effects are mediated through angiotensin I and angiotensin II receptors, both of which are expressed in the normal lung.¹⁶⁸ The pulmonary endothelium represents a major site of ACE expression and angiotensin II production. Notably, ACE2 is a homologue of ACE expressed in the lung that inactivates angiotensin II, leading to the downstream generation of angiotensin I to VII, which acts through angiotensin II receptors to induce vasodilation, serving as a counterbalance to the vasoconstrictive effects of angiotensin II via angiotensin I receptors. Although components of the renin-angiotensin system have been implicated in a variety of lung diseases, including pulmonary hypertension¹⁶⁹ and fibrotic lung diseases, the system has also been strongly linked to the pathophysiologic processes of pulmonary vascular leak syndromes. For example, ACE and angiotensin II have been found to serve a protective role in *acute respiratory distress syndrome* (ARDS), whereas ACE2, angiotensin II, and angiotensin I appear to mediate lung edema and injury associated with ARDS.^{170,171}

LUNG FLUID AND SOLUTE EXCHANGE

TRANSCAPILLARY EXCHANGE AND THE FLUID FLUX EQUATION

The Starling equation describes filtration of fluid across the capillary wall. The equation states:

$$J_v = L_p S [(P_c - P_i) - \sigma d(\pi_c - \pi_i)] \quad (3)$$

where J_v is the net fluid exchange (in cm³/sec), L_p is the hydraulic conductivity of the membrane, S is the surface

area, P_c is the microvascular hydrostatic pressure, P_i is the perimicrovascular hydrostatic pressure, π_c is the microvascular colloid osmotic pressure, and π_i is the perimicrovascular colloid osmotic pressure. The term σ_d is the osmotic reflection coefficient; $\sigma_d = 0$ means that the membrane was freely permeable to the molecules crossing the membrane; $\sigma_d = 1$ means that the membrane “rejected” the molecule, thus being impermeable. Because albumin is the plasma protein with the highest concentration, we consider here primarily the σ_d of albumin. L_pS has been defined as the capillary filtration coefficient.^{172,173}

According to convention, P_c acts outward (i.e., from the vessel to the extravascular space) and P_i acts inward (i.e., from the extravascular space to the vessel), whereas π_c acts inward and π_i acts outward (Fig. 6-9). The direction and magnitude of movement of water across the vessel wall are determined by the sum of hydrostatic and colloid osmotic pressure differences across the wall. $P_c + \pi_i$ constitutes the driving force for filtration, and $\pi_c + P_i$ is the driving force for absorption. The ability of these pressures, called the “Starling forces,” to determine filtration and absorption is dependent on the semipermeable nature of the endothelial barrier—that is, the ability of the endothelial barrier to restrict the free flux of plasma proteins, a characteristic involving the endothelial glycocalyx layer, endothelial basement membrane, and extracellular matrix.^{174,175}

Because P_c decreases along the alveolar capillary, filtration is more likely to take place at the arterial end of the pulmonary capillary, and absorption at the venous end.

Figure 6-9 Schematic representation of the pulmonary capillary tissue-lymphatic system. The Starling forces are microvascular hydrostatic pressure (P_c), microvascular colloid osmotic pressure (π_c), perimicrovascular hydrostatic pressure (P_i), and perimicrovascular colloid osmotic pressure of interstitial fluid (π_i). The alveolar epithelial junctions are tight compared with the interendothelial junctions in the lung and thereby restrict solute transport into the air spaces. The background shading represents plasma proteins in plasma, tissue fluid, and lymph. The lymph flow represents the overflow in the system, that is, the difference between the amount of fluid filtered and the amount reabsorbed. A major determinant of P_c is the precapillary-to-postcapillary resistance ratio as regulated by the smooth muscle tone of the arteries and veins, represented by the narrowings in the precapillary and postcapillary vessels. (From Malik AB: Mechanisms of neurogenic pulmonary edema. *Circ Res* 57:1–20, 1985.)

However, this is an idealized situation, because some vessels only filter fluid and other vessels only absorb fluid. Regional pulmonary capillary pressures can also determine whether vessels filter or absorb fluid. Dilation of a small pulmonary artery increases P_c , and this increases the net transcapillary filtration rate, whereas constriction of a pulmonary artery reduces P_c and increases the net absorption rate. Approximately 2% to 5% of the plasma perfusing the pulmonary circulation is filtered and, of this, 80% to 90% is absorbed back into capillaries and venules. The residual fluid in the extravascular space ultimately enters the lymphatic circulation and thus returns to the circulation.^{62,176}

In the normal lung the Starling forces have the following average values: P_c at midlung level is 10 mm Hg, P_i is –3 mm Hg, π_c is 25 mm Hg, and π_i is 19 mm Hg.⁶² The most accurately known of these pressures is π_c , which is a direct function of plasma protein concentration and thus can be easily determined by an osmometer. The other values are determined indirectly and hence represent best estimates. The summation of the Starling forces in the lung indicates that there is a net outward filtration pressure with filtration across pulmonary vessels exceeding absorption. As noted earlier, P_c and P_i vary according to the height in the lung. In an upright person, both pressures are greater in the dependent regions of the lung than in the lung apex. The forces tending to produce the negative P_i value are the elastic wall tension of vessels and radial traction exerted by the alveolar attachment sites during lung inflation.⁶² Increasing lung volume decreases P_i , whereas reducing lung volume increases P_i because of the reduction of radial traction exerted by alveolar attachment sites.¹⁷⁷

Critical to the Starling model is the transcapillary osmotic pressure gradient ($\Delta\pi = \pi_c - \pi_i$) that is determined by the albumin concentration gradient:

$$\Delta\pi = \sigma_d RT(C_{iv} - C_i) \quad (4)$$

where R is the gas constant, T is the absolute temperature, σ_d is the albumin osmotic reflection coefficient, and C_{iv} and C_i are the intravascular and interstitial albumin concentrations, respectively. The equation indicates that $\Delta\pi$ varies in proportion to the transcapillary albumin concentration difference ($C_{iv} - C_i$). The equation also indicates that the effective $\Delta\pi$ is determined by σ_d , which is dependent on the permeability characteristic of the vessel (see subsequent explanation).

The reflection coefficient (σ_d) defines the permeability of the capillary to the specific molecule. The reflection coefficient is a critical constant in determining the effective $\Delta\pi$ value. The reflection coefficient for albumin, which does not pass freely across the pulmonary endothelial barrier, is 0.8.⁶² Albumin σ_d decreases when endothelial albumin permeability is increased. A decrease in σ_d results in a decrease in $\Delta\pi$, which then becomes less of an absorptive force.

SITES OF FLUID AND SOLUTE EXCHANGE

Capillary Endothelium

The pulmonary microvessel endothelium is continuous and nonfenestrated (eFig. 6-2). The majority of fluid and solute exchanges at the level of the pulmonary microvascular

Figure 6-10 Schematic representation of molecular pathways of transendothelial transport. Shown is the *paracellular pathway* of diffuse transport at intercellular junctions with polar organization of tight and adherens junctions of endothelial cells and interactions of linking proteins that form junctions. Solutes of less than 7.5 nm radius (e.g., albumin is 3.6 nm) can diffuse through junctions.^{180,181} Cell-cell connections include tight junctions composed of transmembrane occluding proteins linked to the actin cytoskeleton by the zona occludens family (ZO-1); adherens junctions mediated by calcium-dependent association of cadherin proteins in turned linked to the α -, β -, and γ -catenin (cat) complex; and platelet-endothelial cell adhesion molecule-1 (PECAM1)-associated junctions. Cell-matrix tethering is maintained by focal adhesion plaques composed of α - and β -integrin transmembrane proteins linked to the actin cytoskeleton by a complex of proteins, including talin, paxillin (Pax), vinculin (Vin), and focal adhesion kinase (FAK).³⁷⁸ The *transcellular pathway* of vesicular (nondiffusive) transport of albumin is shown by either solid- or fluid-phase pathways. The endothelial cell surface expresses albumin-binding proteins (Y) that bind albumin (solid circles).¹⁸⁶⁻¹⁸⁸ Vesicles contain albumin bound to albumin-binding proteins and albumin free in the cytosol. The vesicle membrane fuses with the abluminal cell membrane, and albumin bound to binding protein and free albumin are extruded to the abluminal side (at bottom). GIT1, G protein-coupled receptor kinase interacting protein 1.

endothelium, the layer with the largest surface area available for both diffusion and filtration. Several pathways are available for transport of solutes and water: (1) transcellular pathways (directly across the cell, pathway 1 in eFig. 6-2), (2) vesicular pathways, (3) paracellular pathways (between cells via small or large pores, and (4) plasmalemmal channel pathways (pathways across the cell created by fused vesicles). In addition, soluble molecules such as carbon dioxide and oxygen diffuse rapidly across the entire capillary endothelial surface area. Water also freely crosses the entire surface area of the membrane by means of aquaporin water channels.^{178,179} The molecular basis of the endothelial transport pathways is summarized in Figure 6-10, demonstrating interactions of the paracellular junctions and a specific vesicular pathway.¹⁸⁰⁻¹⁸⁹ In addition, the pulmonary endothelial glycocalyx, significantly thicker than the systemic glycocalyx, forms a substantial *in vivo* endothelial surface layer and structural barrier to solute transport that is critical to inflammation, barrier regulation, and mechanotransduction.^{174,175,190} Prominent components of the endothelial glycocalyx include the proteoglycans heparan sulfate and chondroitin sulfate,¹⁹¹ highly anionic molecules composed of 20% protein and 80% glycosaminoglycans with a molecular weight ranging from 1000 to 4000 kD. Thus the endothelial surface layer serves additional functions in vascular physiology. Factors governing plasma protein transport across the vascular endothelial monolayer are presented in Table 6-1 and subdivided into plasma and hemodynamic forces, properties of

Alveolar Epithelium

Alveolar epithelial type I and type II cells lining the terminal alveoli also serve as a barrier to movement of water and solutes into the alveolar space. The calculated intraepithelial junctional radius of alveolar epithelium is only

approximately 2Å , much smaller than the junctional radius of the pulmonary endothelium,¹ and differs considerably from that in the pulmonary artery.¹⁹² Most lipid-insoluble molecules do not cross the epithelial barrier. Water and ions can penetrate this barrier only to a limited degree, whereas low-molecular-weight lipid-soluble substances such as oxygen and carbon dioxide are freely permeable. The alveolar epithelial barrier is much tighter than the endothelial barrier in terms of fluid flux and has, in addition, an active ion transport function that can actively pump fluid from the alveolar space into the interstitium (see Chapter 9 for more details).

Alveolar-Capillary Septum

The alveolar-capillary barriers have both thin and thick portions (described previously) with the thick septum defined by its larger interstitial space. Fluid and solute exchange takes place primarily in the thick septum because it is the more compliant portion of the barrier. The thin septum is a relatively noncompliant space where endothelial and epithelial cells are virtually fused to each other.⁶²

PULMONARY LYMPHATIC VESSELS

The lung has an extensive network of lymphatic channels involved in fluid and solute drainage and trafficking of lymphocytes and other blood-formed elements. The terminal lymphatics are found in loose areolar tissue surrounding pulmonary vessels and, to some extent, in the thick interstitial septum and are largely confined to the extra-alveolar interstitium.¹⁹³ Fluid that leaks from capillaries in the alveolar walls moves toward the spaces surrounding airways, entering the distal ends of lymphatics.¹⁷⁶ Alveolar wall fluid is propelled by the prevailing pressure gradient away from the alveolus and toward the extra-alveolar space.¹⁹⁴⁻¹⁹⁶ Increases in interstitial fluid volume are handled by increases in pulmonary lymph flow.^{197,198} However, the relationship between interstitial fluid volume and lymph flow is not linear because, beyond a critical fluid volume, pulmonary lymph flow no longer increases in proportion to the increase in fluid volume. This “lymphatic failure” may be related to impairment of the pumping force of lymphatics, constriction of terminal lymphatics by extravascular fluid compression, or compartmentalization of alveolar fluid in areas inaccessible to the lymphatic system. The relative inability to drain the interstitium beyond a certain point is a primary cause of edema formation.^{176,199,200}

LUNG INTERSTITIUM

Interstitial Pressures

Interstitial liquid pressure gradients have been measured from the alveolar wall to the lung hilum¹⁹⁴⁻¹⁹⁶ (Fig. 6-11), and these pressure gradients from the alveoli to hilar interstitial space form the basis for interstitial drainage of the liquid filtered across the microvessels. The filtered fluid moves along the interstitial fluid pressure gradient into the connective tissue surrounding the pulmonary artery, airways, and veins.¹⁷⁶ When fluid filtration exceeds the

Figure 6-11 Pressure gradient in the interstitium of the lung. Fluid from alveolar vessels in the thick septa moves down the pressure gradient to alveolar wall junctions (P_{jct}), to the adventitia surrounding small vessels (P_{adv}), and to the hilum (P_{hilum}). Experiments were done in isolated dog lung with an alveolar pressure of $5\text{ cm H}_2\text{O}$ and a pleural pressure of $0\text{ cm H}_2\text{O}$, and pressures were measured at the hilum, in small vessel adventitia, and at the alveolar wall junction. (Created with data from Staub NC: Pathophysiology of pulmonary edema. In Staub NC, Taylor AE, editors: *Edema*. New York, 1984, Raven, pp 719–746.)

pumping capacity of the lymphatic system, fluid first accumulates in the hilar regions and in sheaths around the large pulmonary vessels,²⁰¹ where pressure is lowest and interstitial compliance is highest. This accounts for the “cuffs” of fluid typically observed around vessels in edematous lungs and that are often visible near the hila in chest radiographs.

Composition of Pulmonary Interstitium

An important component of the pulmonary capillary wall barrier is the endothelial extracellular matrix consisting of a complex array of molecules: laminin, type I and type IV collagen, proteoglycans, fibronectin, and vitronectin.⁶² The three-dimensional arrangement of matrix proteins provides a restrictive barrier to the transport of molecules, and the matrix can sieve molecules of different molecular weights²⁰² and form a dense connective sheath surrounding bronchi and blood vessels, the alveolar septum, and terminal alveoli. The ability of the interstitial matrix to retain water is similar to a sponge where water is incorporated in the dense matrix network of proteoglycans.²⁰³ Albumin is distributed in 60% of the fluid volume as a result of steric and electrostatic exclusion,²⁰⁴ an exclusion that decreases protein diffusion rates through the matrix, in comparison with its diffusion rate in water. Water movement through the interstitial matrix proteins increases as the matrix is hydrated,²⁰⁵ suggesting that increased hydraulic conductivity of lung interstitium during edema may assist in the drainage of water from the interstitial space and thence to the lymphatic vessels (eFig. 6-3).

Interstitial Compliance

The compliance of the lung interstitial tissue is a nonlinear function¹⁹⁵ and has two phases: a low compliance at low interstitial fluid volumes and high compliance during the interstitial edema or alveolar flooding phase. At low levels of tissue hydration, tissue pressure changes markedly in response to a small change in tissue volume, indicative of low tissue compliance. Tissue expands with increased levels

of hydration, and compliance increases dramatically. Compliance increases as the tissue fluid pressure approaches the alveolar pressure. At an interstitial fluid pressure of greater than zero (i.e., values greater than the alveolar pressure), the tissue fluid accumulates with only a small change in the interstitial pressure. The high-compliance portion of the curve may represent the transition from interstitial edema to alveolar edema⁶²; that is, the pressure inflection point may be the maximum interstitial volume before alveolar flooding. This inflection point is seen at a lung weight gain of 35% to 50% and an interstitial pressure of 2 to 3 cm H₂O.⁵⁰ The abrupt increase in compliance attenuates further increases in interstitial hydrostatic pressure. The lung also exhibits regional differences in compliance of the lung interstitium. The interstitial spaces surrounding large vessels or bronchi have higher compliance than the interstitium in the septal region.^{195,206} When the perivascular spaces surrounding extra-alveolar vessels and bronchi are filled with fluid, the interstitial pressures equilibrate throughout the interstitial space. The continuing high level of fluid filtration then increases interstitial pressure to a critical level, and the epithelial barrier is breached (potentially facilitated by injury to the alveolar epithelium), resulting in rapid alveolar flooding.⁶²

PATHOGENESIS OF PULMONARY EDEMA

PHASES AND SITES OF EDEMA ACCUMULATION

Pulmonary edema is defined as the accumulation of water in the lung extravascular spaces and is a sequential process initially developing in the hilar region of the lungs followed by fluid filling of the interstitial compartment and finally resulting in fluid entering alveoli in an all-or-nothing manner.^{201,207} Vertical pressure gradients within the pulmonary circulation, the result of differences in hydrostatic pressure in pulmonary microvessels at different lung heights, vertical pleural fluid pressure, and regional lung volume, produce a greater capillary hydrostatic pressure in the dependent lung regions that favors edema formation in these regions. Although greater lung water content is predicted in the dependent lungs, no such vertical gradient has been found by either measurement of extravascular lung water content or morphometric determinations of the interstitial space.^{62,208-210} Fluid that cannot be cleared by the lymphatic channels accumulates in the connective tissue surrounding smaller vessels and bronchioles²⁰⁷ and migrates down the interstitial fluid pressure gradient to interstitial spaces around larger vessels and airways and becomes compartmentalized, forming perivascular cuffs.²¹¹ After an increase in the interstitial fluid volume from 35% to 50%, individual alveoli begin to flood in an all-or-nothing manner¹⁹⁵ with the distribution of alveolar flooding patchy but followed by rapid flooding. These abnormalities explain the characteristic sequential impairments of gas exchange in pulmonary edema (see Chapter 62), with alveolar flooding a cataclysmic event that results in impaired gas exchange, arterial hypoxemia, and respiratory failure. The sequence of pulmonary edema formation¹⁷⁶ reflects a

breakdown of the normal homeostatic mechanisms that maintain lung fluid balance.¹⁷⁶ The characteristics of fluid exchange between the vascular space and interstitium of lungs have been reviewed,^{62,176} as have the factors regulating pulmonary vascular endothelial permeability,²¹² and are detailed below.

Starling Forces in Pulmonary Edema Formation

Increases in lung vascular permeability are operationally defined in the Starling equation by an increased capillary filtration coefficient (LpS), which indicates decreased resistance to water flow across the capillary wall barrier, and a decreased albumin reflection coefficient (σ_{alb}), which describes the albumin permeability of the vascular endothelial barrier. The critical functional definition of increased lung vascular permeability is the extravasation of protein-rich fluid into the interstitial space²⁰⁷ and ultimately into the alveolar space, resulting in fulminant pulmonary edema. In high-permeability pulmonary edema, the alveolar fluid protein concentration approximates the plasma protein concentration, whereas in hydrostatic edema (i.e., edema resulting from increase in the pulmonary capillary hydrostatic pressure), the ratio of plasma to alveolar fluid protein concentration is usually less than 0.6.⁶²

Pulmonary Capillary Pressure and Plasma Osmotic Pressure in Edema Formation

The relationship between left atrial pressure and the rate of formation of pulmonary edema is shown in Figure 6-12. For left atrial pressures up to 20 to 25 mm Hg, water content does not increase in the normal lung²¹³ because fluid accumulation is minimized by “safety factors.”⁶² When capillary hydrostatic pressure increases above a critical value, the pulmonary extravascular water content increases progressively as a result of the inability of these safety factors to

Figure 6-12 Graph showing the rate of edema formation as a function of left atrial pressure. In the normal lung (solid line), edema does not form until left atrial pressure exceeds 20 to 25 mm Hg. Above this pressure, edema forms slowly at first, and then more rapidly at higher pressures. If the endothelium is damaged (dashed line) or if plasma colloid osmotic pressure is reduced, edema begins to form at lower left atrial pressures and at a more rapid rate. (From Guyton AC, Lindsay AW: Effect of elevated left atrial pressure and decreased plasma protein concentration in the development of pulmonary edema. *Circ Res* 7:649–653, 1959.)

reduce fluid filtration rate. The primary safety factors acting at the capillaries are the increase in lymph flow; decrease in π_i , which results from greater transcapillary flux of water than protein; increase in P_i ; and decrease in the albumin exclusion volume (see later). These changes serve to minimize the increase in the extravascular lung water content when left atrial pressure is increased.

In contrast, decreases in the plasma protein concentration can contribute to edema formation. These events reduce the absorptive pressure (π_c) and thus increase the net transcapillary filtration pressure. Importantly, the critical capillary pressure at which lungs begin to gain water decreases in direct proportion to the reduction in plasma osmotic pressure.⁶²

Lymphatic Insufficiency and Edema Formation

The lymphatic vessels are capable of removing excess extravascular fluid because of their effectiveness as pumps. Lymphatic propulsion is determined by the intrinsic contractility of lymphatic vessels, by the pumping action of inspiration and expiration, and by lymphatic valves, which account for the unidirectional lymph flow.²⁰⁷ Lymphatics, however, have a limited capacity to increase lymph flow. Beyond their critical capacity, lymph flow does not increase in direct proportion to the increase in interstitial fluid volume and may actually decrease because of compression of the lymphatic channels.²¹⁴ The extent to which lymphatic insufficiency serves as an important mechanism of fluid accumulation in the lung is not clear. Some studies have indicated that surgical removal of the lymphatics predisposes the lung to edema, although the increase in water content is usually transient.²¹⁵

Safety Factors in Lung Fluid Homeostasis

The safety factors cited in the discussion of increased pulmonary capillary pressure become operative when fluid begins to accumulate in the interstitial space. When fluid accumulates in the interstitial space, there are two consequences that serve to decrease π_i : one consequence is that the excess fluid decreases the albumin concentration directly and thus decreases π_i ; the other consequence is that the excess fluid alters the interstitial matrix proteins and decreases the albumin exclusion volume, further decreasing π_i .⁶² The *exclusion volume of albumin* is the volume of the interstitium from which albumin is excluded by matrix proteins. If the exclusion volume increases, albumin is concentrated in the remaining interstitial fluid, thereby raising π_i ; if the exclusion volume decreases, albumin is distributed in a larger interstitial volume, thereby lowering π_i . Albumin is normally excluded from approximately 40% of the pulmonary interstitial space by the matrix proteins collagen, hyaluronic acid, and laminin.⁶² An increase in the interstitial fluid volume disrupts the structure of interstitial matrix proteins (see eFig. 6-3); thus the volume available for albumin distribution increases. The albumin protein concentration decreases to a greater extent because of this decrease in albumin exclusion volume. Therefore the increase in the albumin distribution volume amplifies the decrease in π_i , which would not drop to the same extent without this concomitant decrease in the exclusion volume. Examination of the effect of albumin exclusion on the colloid osmotic pressure when

the interstitial fluid volume is increased (see eFig. 6-3) reveals that for the same increase in the interstitial fluid volume, the interstitial osmotic pressure is lower when albumin exclusion is decreased.⁶²

In addition, the role of the bronchial circulation may modulate lymph clearance under basal conditions and after lung injury.^{125,216,217} Movement of interstitial fluid across the visceral pleura into the pleural space is a further means of clearance of edema fluid from the lung and can be considered another safety factor.²¹⁸

Effects of Cellular and Molecular Charge

The intact endothelial cell membrane is nonthrombogenic due to release of prostacyclin and the meshwork of glycoproteins (glycosaminoglycans²¹⁹⁻²²²) forming the endothelial glycocalyx,^{223,224} which accounts for the negatively charged anionic endothelial cell surface layer. The selective permeability of the endothelial barrier to plasma proteins such as albumin is related in part to the anionic charge of the albumin molecule as well as to the surface charge on the endothelial cell. Surface negative charge disruption results in albumin “leakage” across the capillary-matrix complex.²²⁵ Endothelial cell membrane surface charges influence albumin transport with an isoelectric point of 4.1.²²⁰ The distribution of charge sites provides a means of preferentially gating albumin across the endothelial monolayer. Another charge-related effect is the negative charge distribution of interstitial macromolecules (heparan sulfate, chondroitin sulfate, and other complex proteoglycans) leading to albumin repulsion and increased transport through specific matrix domains.²²⁶⁻²²⁸

Because of the negative albumin charge, albumin permeability is greater than predicted from its molecular size. For example, dextran sulfate (negatively charged dextran, molecular weight 500 kd) is threefold more permeable than neutral dextran of the same molecular weight. Sheep lung lymph studies also indicate plasma-to-lymph transport of negative dextrans across the pulmonary endothelial barrier is greater than neutral dextran transport.²²⁸ Thus the negatively charged molecules are preferentially transported across the endothelial barrier because of charge-related gating phenomena, despite the net negative charge of endothelial cell membranes.²²⁸

Regional Differences in Endothelial Permeability

Endothelial cell heterogeneity confers specific properties that distinguish endothelium from large vessels and from small vessels within an organ and among those from different organs (e.g., between the blood-brain barrier and pulmonary endothelium).^{219,229} The albumin permeability in pulmonary microvascular endothelium is one half to one fifth the values of similar endothelium from the main-stem pulmonary artery, a feature noted in vivo.²³⁰ Microvascular endothelium is significantly more restrictive to sucrose and inulin than large-vessel endothelium, indicating that transport via paracellular pathways is reduced to a greater degree. Microvascular endothelium also proliferates at a higher level than large-vessel endothelium and retains phenotypically distinct calcium and cyclic nucleotide signaling responses.²²⁹ Endothelial studies from different vascular sites have identified organ-specific antigens on microvascular endothelium that may be responsible for differential

degrees of permeability in regional vascular beds.²²⁹⁻²³¹ Phenotypic differences in lectin-binding domains of pulmonary endothelium from different vascular beds (*Ricinus communis* agglutinin and peanut agglutinin) are related to permeability characteristics.^{232,233}

MECHANISMS OF INCREASED ENDOTHELIAL PERMEABILITY

As depicted in [Figure 6-10](#), two general pathways describe the movement and flow of fluid, macromolecules, and leukocytes into the interstitium and subsequently into the alveolar air spaces, to produce clinically significant pulmonary edema during lung inflammation (see [eFig. 6-2](#)). The *transcellular pathway* uses a tyrosine kinase-dependent, glycoprotein 60-mediated transcytotic albumin route whose regulation and function may serve to uncouple protein and fluid permeability.^{234,235} However, there is general consensus that in the context of inflammatory lung injury, the primary mode of fluid and transendothelial leukocyte trafficking is by the *paracellular pathway*,²¹² as shown by electron microscopy studies that demonstrate the formation of paracellular gaps at sites of active inflammation within the vasculature.^{236,237} The mechanisms that mediate alterations in pulmonary vascular endothelial permeability as a result of a variety of mechanical stress factors, inflammatory mediators, and activated neutrophil products (such as reactive oxygen species, proteases, and cationic peptides) have been discussed earlier. Fortunately, there has been progress in identifying agents capable of reversing or restoring vascular integrity with therapeutic potential in acute and chronic inflammatory lung diseases.²³⁸ In the following sections, important mechanisms contributing to the increase in pulmonary vascular permeability are discussed and covered in greater detail in the cited reviews.^{212,239}

Characteristics of Increased Vascular Endothelial Permeability

A variety of bioactive agonists, cytokines, growth factors, and mechanical forces alter pulmonary vascular barrier properties and increase vascular permeability.^{111,212,240-246} The serine protease thrombin represents an ideal model for the examination of agonist-mediated lung endothelial activation and barrier dysfunction (see [Fig. 6-8](#)) because it evokes numerous responses that regulate hemostasis, thrombosis, and vessel wall pathophysiologic characteristics and is recognized as an important mediator in the pathogenesis of ARDS.²¹² Thrombin increases vascular leakiness to macromolecules by ligation and proteolytic cleavage of the extracellular domain of PAR1, a member of the proteinase-activated receptors.²⁴⁷ The cleaved receptor, acting as a tethered ligand, activates and initiates a number of downstream effects²⁴⁷⁻²⁵¹ (see [Fig. 6-8](#)). Thrombin binding without receptor cleavage fails to elicit the complex signaling cascade that increases endothelial permeability.²⁴⁹ The effect of thrombin on endothelial permeability is rapid (within 2 minutes) and reversible²⁴⁵ and critically dependent on G protein-transduced signals^{115,212} that increase cytosolic calcium and activate the contractile apparatus, a common feature of other inflammatory mediators as well.^{111,212,240-244}

Cytoskeletal Alterations

Majno and Palade²³⁷ first observed that lung endothelial cells exhibit a rounded form, producing paracellular gaps during inflammatory edema. This profound conformational change and subsequent disruption in the integrity of the endothelial cell monolayer is now recognized as a cardinal feature of inflammation.^{245,246,252-255} The formation of paracellular gaps implicates the direct involvement of endothelial structural components composed of cytoskeletal proteins (microfilaments, microtubules, intermediate filaments).²¹² A useful paradigm to understand cytoskeletal influences on vascular barrier regulation involves a balance of competing forces: adhesive cell-cell and cell-matrix tethering forces (promoting monolayer integrity) and contractile forces (generating centripetal tension).²¹² This equilibrium is intimately influenced by the dynamic actin-based endothelial cytoskeleton via actin-binding proteins (capping, nucleating, and severing proteins), which are critical participants in cytoskeletal rearrangement, tensile force generation, and regulation of endothelial junctional stability.²¹² Polymerized actin fibers (or F-actin) confer strength to structural elements regulating cell shape, particularly when accompanied by phosphorylated myosin within peripherally distributed cortical bands.²¹² These elements are essential for maintenance of endothelial integrity and basal barrier function. Edemagenic agents, such as thrombin, initiate cytoskeletal rearrangement characterized by the loss of peripheral actin filaments with a concomitant increase in organized F-actin cables that span the cell as “stress fibers” to increase intracellular tension.²⁴⁵ Cytoplasmic stress fibers form via the coordinate activation of the small GTPase Rho and calcium/calmodulin-dependent MLCK, which together increase the level of phosphorylated *myosin light chains* (MLCs) in a spatially distinct manner (see [Fig. 6-8](#)).^{115,241,256-258} The resultant increases in stress fiber formation and actomyosin cellular contraction disrupt the barrier-regulatory balance and destabilize cytoskeletal-junctional linkages, culminating in increased vascular permeability (see [Fig. 6-8](#)). Consistent with this model, thrombin-induced permeability and intercellular gap formation disrupt the integrity of paracellular adherens junctions and reorganization of focal adhesion plaques.^{241,259-262} Inhibition of MLCK or Rho kinase or calcium antagonism attenuates agonist-induced MLC phosphorylation, gap formation, and barrier dysfunction²⁵⁶⁻²⁵⁸ in many models of lung edema.^{241,242,255,263-269}

Microtubules are polymers of α - and β -tubulin that also contribute to barrier regulation.²⁷⁰⁻²⁷⁵ They form a lattice network of rigid hollow rods spanning the cell, undergoing frequent assembly and disassembly,^{276,277} and exhibit complex but intimate functional interactions with actin filaments during dynamic cellular processes.²⁷²⁻²⁷⁸ Microtubule disruption with agents such as nocodazole or vinblastine induces rapid assembly of actin filaments and focal adhesions,^{272,273,278} isometric cellular contraction²⁷² that correlates with the level of MLC phosphorylation, increased permeability across endothelial cell monolayers,^{272,273,278} and increased transendothelial leukocyte migration,²⁷⁸ events that can be reversed or attenuated by microtubule stabilization with paclitaxel. Microfilament-microtubule crosstalk represents an intriguing area of endothelial cell

barrier regulation.²⁷⁹ The function of intermediate filaments in endothelial cell barrier regulation is much less defined,²¹² although recent studies have highlighted the consequence of redistribution of vimentin, an intermediate filament protein, in barrier stabilization in hypoxic endothelium.²⁸⁰

Besides receptor-mediated pathways, mechanical signals are also transduced to the endothelial cytoskeleton^{87,111} via, in part, the complex array of proteins of the lung endothelial glycocalyx. Nuclear magnetic resonance techniques have demonstrated that cell surface proteoglycans behave as viscoelastic anionic polymers, undergoing shear-dependent conformational changes that may function as blood flow sensors to transduce signals into endothelial cells.²⁸¹ Components of the glycocalyx, such as heparan sulfate proteoglycans and sialoproteins, modulate cell-cell and cell-matrix adhesions via effects on the cytoskeleton and represent endothelial surface-binding domains for inflammatory cationic peptides.^{282,283} Syndecan is a heparan sulfate proteoglycan that has been shown to influence cytoskeletal organization, cell-cell adhesion, and motility;²⁸³ syndecan mediates cationic peptide-induced signaling that, via syndecan-1 and syndecan-4 clustering and actin stress fiber formation, leads to cytoskeletal rearrangement and barrier dysfunction.²⁸² This provides a mechanistic basis for activated neutrophil-derived cationic peptide-induced increases in vascular permeability.^{244,284}

Intracellular Calcium Shifts and Other Barrier-Regulatory Signals

Increases in vascular permeability are signaled in many edemagenic models by a rapid initial rise in intracellular calcium^{240,255,285} followed by a second phase of slow decay.^{246,248,286,287} The initial calcium rise in endothelial cells is caused by mobilization from intracellular stores in response to increased inositol 1,4,5-triphosphate generation (derived from phospholipase C-activated hydrolysis of phosphoinositides).^{286,288} The second phase is caused by calcium influx through store-operated channels²⁸⁷ and is critical to increases in permeability.^{285,289} Direct increases in intracellular calcium (by calcium ionophore) increase endothelial albumin permeability,²⁶⁷ decrease transendothelial electrical resistances,²⁶⁵ and increase hydraulic conductivity of intact microvessels.^{248,257,267,288} Increased intracellular calcium signals cytoskeletal rearrangement via actin polymerization/depolymerization that requires activation of calcium-dependent kinase systems (e.g., MLCK, calcium/calmodulin-dependent kinase II, protein kinase C)²⁹⁰⁻²⁹³ and subsequent phosphorylation of key cytoskeletal proteins involved in endothelial barrier regulation (vimentin,^{290,294} caldesmon,²⁹⁴ β -catenin,²⁶¹ vinculin,²⁶² α -actinin,²⁹⁵ MLC,²⁵⁷ filamin,²⁹¹ cortactin,²⁹⁶ vasodilator-stimulated phosphoprotein,²⁹⁷ microtubule-associated proteins).²⁷⁸

Alternate pathways exist that do not require increased MLC phosphorylation and are involved in barrier regulation. For example, protein kinase C, a family of serine/threonine kinases comprising at least 12 isotypes,^{294,298} is causally linked to phosphorylation of cytoskeletal proteins such as caldesmon, an actin-, myosin-, and calmodulin-binding protein present in actomyosin cross-bridges and stress fibers.²⁹⁴ Finally, p60src kinase and p38 mitogen-

activated protein kinase activation regulate endothelial stress fiber formation and contractile regulation, endothelial cell migration, and both vascular endothelial growth factor- and cytokine-induced permeability.^{241-243,296,299-301}

Focal Adhesions and Extracellular Matrix Components

Cell-matrix adhesions are essential for barrier maintenance and restoration and exist in dynamic equilibrium with endothelial contractile forces. An organized basement membrane and extracellular matrix surrounding the endothelium³⁰² may control transendothelial solute flux, and this may be dependent on particular extracellular matrix constituents (e.g., certain matrix proteins are known to restrict albumin transport because of the negative charge of their glycosaminoglycan constituents).³⁰³ In vivo studies indicate that the interstitial matrix is capable of a 14-fold reduction in diffusive transport of albumin.

Endothelial focal adhesions are composed of extracellular matrix proteins (collagen, fibronectin, laminin, vitronectin, proteoglycans), transmembrane integrin receptors, and cytoplasmic focal adhesion plaques (containing α -actinin, vinculin, paxillin, and talin), which combine to provide additional adhesive forces in barrier regulation and form a critical bridge for bidirectional signal transduction between the actin cytoskeleton and the cell-matrix interface^{302,304} (see Fig. 6-7). The core matrix proteins, because of position and points of contact with endothelium, may determine cell-substratum adhesion²²⁵ and vascular permeability in normal conditions and in response to inflammatory mediators.³⁰⁵ Extracellular stimuli can be transmitted to the cytoskeleton through focal adhesion rearrangement linked to integrin ligation, which directly influences endothelial attachment, cell spreading, and permeability.³⁰⁶ Integrin binding to the extracellular matrix induces the attachment of integrins to intracellular actin fibers, a process that stimulates tyrosine phosphorylation of multiple focal adhesion proteins as well as tyrosine phosphorylation-dependent calcium influx.^{307,308} The extracellular matrix can also be remodeled by endothelial cell-released proteases, causing endothelial cells layered on this matrix to become more permeable.³⁰⁵ Integrin β_4 is a key mediator of the attenuation of lung inflammatory responses by statins and is linked to activation of Rac1 GTPase. Additional β integrins are increasingly recognized as important regulators of endothelial cell barrier function and include β_3 and β_5 .^{309,310}

Endothelial Water Permeability and Albumin Transcytosis

The pulmonary vascular endothelium provides the primary resistance to the transvascular flow of water,³⁰³ although the relative distribution of transcapillary water flow through the paracellular and transcellular pathways remains controversial.^{236,225,311} Albumin is a major determinant of endothelial water permeability because the interaction of albumin with the vessel wall regulates vessel wall hydraulic conductivity.^{311,312}

Receptor-mediated transcytosis of solutes is an important mechanism of transport across the pulmonary microvascular endothelial barrier. The transendothelial flux of proteins such as albumin, insulin, and transferrin involves

recognition by receptors located on the luminal side of the endothelial cell^{187,313-317} (see Fig. 6-10). Albumin binds to the endothelial cell surface protein glycoprotein 60 on the luminal side of the endothelium^{187,313,314,315-318} signaling (via tyrosine kinase activities) the formation of vesicles²³⁴ with albumin shuttling from the luminal to abluminal cellular sites.^{187,313,315,319} In addition, there may be transport of albumin from the abluminal to the luminal side of the endothelial monolayer,^{233,319} presenting an intriguing potential for an active mechanism of albumin transport. Albumin binding to endothelial cells is reversible.^{186,320,321} Albumin binds with a higher affinity in pulmonary microvessel endothelial cells,³¹⁴ consistent with the greater number of vesicles present in these cells.

Apoptosis and Endothelial Cell Dysfunction

Pulmonary endothelial cells have relatively low turnover rates due in part to protective effects of physiologic mechanical forces, including shear stress and cyclic stretch. However, because of the positioning of the endothelium at the surface of blood and tissue, endothelial cells are constantly exposed to multiple biochemical and biophysical stresses, such as endotoxins, tumor necrosis factor- α , oxidative stress, and excessive mechanical stress that potentially initiate apoptosis, or programmed cell death. Apoptotic cells undergo a well-ordered morphologic and molecular pattern of death, including cytoskeletal rearrangement, membrane blebbing, nuclear condensation, DNA fragmentation, and cell shrinkage (see cited review).³²² Usually, apoptotic cells do not elicit an inflammatory response and are phagocytosed by neighboring cells. In contrast, cells undergoing necrosis demonstrate cellular and nuclear swelling, often accompanied by inflammation in damaged tissues.

If damage is limited to a small fraction of the endothelial cell lining, viable neighboring cells can spread to cover the damaged space and thereby attenuate procoagulant effects. Extensive damage, however, results in extensive endothelial loss, exposing the damaged basement membrane to platelets and subsequent thrombosis. Extrinsic and intrinsic pathways share mechanisms using the aspartate-specific cysteinyl proteases (caspase) cascades. The best characterized extrinsic pathways are the binding of FAS ligand to FAS receptors³²³ and tumor necrosis factor- α to tumor necrosis factor receptor 1,³²⁴ which trigger the caspase cascade. FAS/FAS ligand-mediated lung apoptosis has been implicated in acute lung injury and ARDS.^{325,326} In contrast, the intrinsic pathway may be initiated upon exposure to stresses, such as cytotoxic drugs, oxidants, radiation, and growth factor deprivation, which result in mitochondria release of several apoptogenic proteins into the cytosol such as cytochrome *c*, which serves to activate caspase-9. A common mediator of endothelial cell injury is neutrophil-generated ROS, either alone or combined with nitric oxide to form peroxynitrite. ROS is catalyzed by the enzyme phagocyte oxidase, expressed by neutrophils and macrophages, whereas vascular cells express the homologous nonphagocyte oxidase. These oxidative stresses can cause barrier dysfunction and may antagonize tumor necrosis factor responses.³²⁷ Several preclinical studies have targeted apoptosis in novel therapeutic strategies for preserving the pulmonary vasculature.³²⁸

STRATEGIES TO REVERSE PERMEABILITY AND RESTORE BARRIER INTEGRITY

Significant progress in understanding the molecular and cellular events regulating lung vascular permeability has led to the development of novel therapeutic agents for modulating barrier function in a clinically advantageous way.

The endothelial barrier can be enhanced and protected by angiogenic growth factors (hepatocyte growth factor,³²⁹ angiopoietin,³³⁰ sphingosine-1-phosphate [S1P]).^{271,329-332} For example, S1P, a sphingolipid metabolite generated by numerous cell types, including endothelium and platelets, is a potent endothelial cell chemotactic and angiogenic factor producing robust and sustained enhancement of the endothelial barrier.^{300,331,333,334} Ligand of the S1PR1 receptor by S1P strongly enhances lung vascular barrier function in vitro^{331,335} and in vivo^{336,337} and produces highly significant reductions in multiple indices of endotoxin- and radiation-induced inflammatory lung injury, including vascular leak, demonstrated in both murine^{336,337} and canine³³⁶ ARDS models. This profound barrier enhancement is mediated by G protein-dependent signaling cascades, which lead to cytoskeletal rearrangement and increased endothelial junctional integrity (see Fig. 6-7).^{331,338,339} The S1PR3 receptor, in contrast, activates Rho GTPase, produces barrier disruption, and is released in lung endothelial exosomes by inflammatory processes; it may serve as a novel biomarker and predictor of survival in ARDS.³⁴⁰

Other barrier-promoting agonists include the S1P analogue, FTY720, statins, activated protein C, adenosine triphosphate, high-molecular-weight hyaluronan, methyl-naltrexone, and oxidized phospholipids (for review, see Chiang and Garcia³⁴¹). FTY720, an unphosphorylated S1P analogue, is a Food and Drug Administration-approved immunosuppressant for multiple sclerosis and produces lymphopenia via inhibition of cellular egress from lymphoid tissues.³⁴² However, intraperitoneal FTY720 protects against lipopolysaccharide-mediated murine acute lung injury.³³⁷ As noted above, simvastatin, a 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor, improves lung endothelial barrier function in lipopolysaccharide and ventilator-induced lung injury models of lung injury, as well as in radiation-induced lung permeability,³⁴³ through activation of an Rac1-dependent cytoskeleton mechanism that is independent of cholesterol-lowering effects.³⁴⁴ Activated protein C, a previously Food and Drug Administration-approved anticoagulant for severe sepsis, also enhances vascular barrier function in vitro and in vivo^{345,346} but was withdrawn for lack of efficacy.³⁴⁷ Adenosine triphosphate induces barrier enhancement via phospholipase C- and Rac1-dependent cytoskeleton reorganization,^{348,349} conferring protection from endotoxin-induced lung injury.³⁵⁰ Both activated protein C, via the endothelial protein C receptor, and high-molecular-weight hyaluronan, via the CD44 receptor, transactivate S1PR1 to induce AKT1- and Rac1-dependent barrier enhancement.³⁵¹ Oxidized phospholipids also confer barrier enhancement through activation of Rac1- and CDC42-dependent pathways³⁵² and are protective in murine models of ventilator-induced lung injury.³⁵³ These novel agents that preserve or restore vascular integrity offer promise for the future management of

increased vascular leak in the critically ill and await translation to clinical practice.

PULMONARY VASCULAR GENOMICS AND GENETICS

Understanding the genetic and epigenetic basis of pulmonary vascular disease offers the potential for valuable insights into the functional significance of individual genes in normal lung physiology and in complex lung diseases characterized by vascular dysfunction. For example, expression profiling of tumor-associated murine lung endothelial cells produced a six-gene inflammatory gene signature that significantly predicted reduced survival in humans with breast cancer, colon cancer, and lung cancer, indicating the potential role for lung vascular endothelial gene expression and variation in the prognosis of human cancers.³⁵⁴ Pulmonary hypertension genomics and genetics are discussed in Chapter 58.

ARDS represents the ultimate in genetic stress and an unparalleled derangement in lung vascular function. Early genetic studies identified mutations in the gene encoding ACE, an enzyme extensively expressed in pulmonary endothelium to regulate angiotensin II production. These ACE mutations, which correspond with variance in plasma ACE activity,³⁵⁵ increased risk and poor prognosis in ARDS in European-descent populations.³⁵⁶ Genomic-intensive approaches with expression profiling of lung tissues from preclinical models of ARDS and ventilator-induced lung injury have successfully identified novel ARDS candidate genes. For example, these studies identified an obscure cytokine, pre-B-cell colony-enhancing factor, encoded by *NAMPT* and also known as NAMPT and visfatin,^{357,358} as a novel biomarker in preclinical and human studies of ARDS.³⁵⁹ *NAMPT*/pre-B-cell colony-enhancing factor induces increased lung endothelial permeability,³⁶⁰ and gene sequencing identified a single nucleotide polymorphism haplotype that altered a transcription factor-binding site for signal transducer and activator of transcription 5, conferring increased susceptibility to excessive mechanical stress and ARDS mortality.³⁵⁹ Subsequent studies focusing on genes highly relevant to regulation of vascular barrier function³⁶¹ have validated single nucleotide polymorphisms that confer risk for developing ARDS and that influence ARDS mortality³⁶²⁻³⁶⁶ and have highlighted important racial differences in minor allelic frequencies, a finding relevant to the disproportionate morbidity and mortality rates observed in Hispanic and African Americans.³⁶⁷ This health disparity, although reflecting differences in socioeconomic status and access to care, also implicates epigenetic/genetic variation as a risk factor.³⁶⁸ For example, a trio of coding single nucleotide polymorphisms in *MYLK*, the barrier-regulatory gene encoding MLCK (discussed earlier), are rare in European descendants but frequent in those of African descent, and confer susceptibility to ARDS³⁶⁹ and risk for severe asthma in African Americans.^{370,371} Similarly, the functional rs2814778 polymorphism in the gene encoding the Duffy antigen/chemokine receptor is associated with worse clinical outcomes among African Americans with

ARDS,³⁶⁸ and single nucleotide polymorphisms in *ANGPT2*, encoding angiotensin-2, the natural antagonist for angiotensin-1, are implicated in pulmonary vascular leak syndromes and confer increased risk for trauma-associated ARDS in an African descent cohort. Additional ARDS-associated genes plausibly related to vascular pathobiologic changes include *S1PR1*, *S1PR3*,³⁷² *IL6*,³⁷³ *IL10*,³⁷⁴ *DIO2* (encoding an iodothyronine deiodinase), macrophage migration inhibitory factor or *MIF*,^{375,376} and vascular endothelial growth factor (*VEGF*).^{361,377} The study of the genetic contribution to ARDS pathogenesis, severity, and response to therapy remains a nascent, albeit exciting, field that may define novel biomarkers and therapeutic targets in disorders of the pulmonary circulation.

ACKNOWLEDGMENTS

The author is grateful to Alexander N. Garcia, who did an enormous amount of work preparing the background for this chapter.

Key Points

- The pulmonary circulation serves both respiratory and hemodynamic functions contributing to gas exchange in the terminal respiratory units.
- Gravity profoundly affects the distribution of blood flow within the lung.
- The juxtaposition of capillaries with alveoli provides the vast surface area needed for effective gas exchange; this arrangement is a unique feature of the lung microcirculation.
- The pulmonary circulation is a low-pressure, low-vascular-resistance circulation functionally different from the systemic circulation.
- Pulmonary vessels vasoconstrict in response to hypoxia, whereas systemic vessels vasodilate.
- Pressure and flow are highly pulsatile throughout the pulmonary circulation.
- A variety of pathophysiologic events and mediators produce either hydrostatic or high-permeability pulmonary edema.
- Vascular integrity is dependent upon the endothelial cell monolayer and is influenced by the negatively charged glycocalyx, by cell-cell apposition, and by the cell-cell matrix interactions.
- A leaky pulmonary microvasculature is intimately linked to the endothelial cytoskeleton.
- Genomic and genetic factors influence pulmonary circulation responses such as the development of vascular permeability in a racial- and ethnic-specific fashion.

eFIGURE IMAGE GALLERY

eFigure 6-1 Schematic illustration of the components of the bronchial circulation. Flow from capillary beds supplying large airways and lymph glands drains to bronchial veins and into the azygos vein and superior vena cava. Intrapulmonary flow drains into the pulmonary circulation at the level of the alveoli (bronchopulmonary anastomoses) or pulmonary veins (bronchopulmonary veins). (From Deffebach ME, Charan NB, Lakshminarayan S, Butler J: The bronchial circulation. *Am Rev Respir Dis* 135:463–481, 1987.)

eFigure 6-2 Schematic representation of hypothetical pathways of transport in continuous endothelium: 1, transcellular pathway; 2, vesicular pathway; 3, small- and large-pore pathway; and 4, fused plasmalemmal channel pathway. BM, basement membrane; E, endothelial cell. See eTables 6-1 and 6-2 for detailed explanation.

eFigure 6-3 A, Schematic diagram showing the pulmonary interstitial matrix. Normally protein is excluded from 40% of the interstitial space. When interstitial water content increases, the matrix is disrupted and the exclusion volume decreases, making more of the matrix accessible to proteins. The increased distribution volume helps to maintain a lower concentration of protein and decreased colloid osmotic pressure than otherwise and constitutes an important edema safety factor opposing filtration. **B**, With an increase in interstitial volume (V_i), the colloid osmotic pressure (π_i) of extravascular proteins decreases. The *solid line* represents the decrease in π_i by dilution of a fixed interstitial space. The *dashed line* represents the decrease in π_i when the exclusion volume decreases with increasing V_i . eTable 6-1 Routes of Endothelial Transport of Lipid-Insoluble Molecules

TRANSCELLULAR (CELL MEMBRANE)

Consists of three barriers in series (plasma membrane, cytoplasm, plasma membrane).

VESICLES

Involves equilibration of luminal and abluminal fluids. Transport may be dependent on concentration gradient and rate of vesicular turnover.

SMALL AND LARGE "PORES"

Continuous route exists from the luminal to the abluminal sides. Flux of water and solutes across these pathways can be diffusive and convective.

Diffusive and convective transport may be coupled. Molecular sieving (i.e., restriction of solute permeation as molecular size approaches the pore dimension) is a characteristic of pore pathways.

FUSED PLASMALEMMAL CHANNELS

Created by transient fusion of two or more vesicles. Exhibit the same characteristics as junctional large pores.

eTable 6-2 Physical Characteristics of Tracer Molecules Used to Determine Selectivity of the Pulmonary Vascular Endothelial Barrier

Molecule	Molecule Weight (kd)	Stokes-Einstein Radius (Å)	D_{37}^*
Mannitol	0.182	4.4	0.9
Sucrose	0.342	5.2	0.721
Inulin	5.5	11–15	0.296
Cytochrome c	12	16.5	0.13 [†]
α -Thrombin	36.6	28	0.08 [‡]
Ovalbumin	43	27.6	0.11
Albumin (BSA)	69	36.1	0.093
Plasminogen	82	45.1	0.043
Fibrinogen	340	106	0.033

*Diffusion coefficient in water at 37° C = $D_{37} \times 10^{-5}$.

[†]Free diffusion coefficient in water at 20° C.

[‡]Free diffusion coefficient in water at 27° C.

FUNDAMENTAL CONCEPTS

As pulmonary physicians have become increasingly involved in the care of critically ill patients, a thorough understanding of acid-base metabolism has become indispensable. Regulation of arterial pH is a critical factor in maintaining stable extracellular fluid and intracellular acid-base homeostasis. Arterial pH is kept under tight control by both pulmonary and renal mechanisms, each of which must also regulate other processes such as gas exchange in the lungs and fluid and electrolyte balance by the kidneys. Although arterial pH is usually well guarded, it can be preempted by other priorities. For example, hypoxia stimulates the carotid bodies, resulting in hyperventilation and respiratory alkalosis. Furthermore, metabolic alkalosis is often perpetuated by the renal response to contraction of the extracellular volume in patients who have had severe vomiting.

Understanding how respiratory and metabolic mechanisms interact to govern pH has been complicated by the introduction of a bewildering assortment of conflicting acid-base approaches. The relative merits of each must be judged in terms of carefully selected chemical definitions and concepts, which are briefly considered in this chapter. This is followed by a review of some of the more important disorders of acid-base balance.

ACID-BASE CHEMISTRY

pH Versus H^+

In aqueous solutions, “free” hydrogen ions (protons) are associated with clusters of water molecules, but for convenience these are designated as H^+ or H_3O^+ . Rather than expressing acidity in terms of H^+ concentration ($[\text{H}^+]$, normally 35 to 45 nanomoles/L in plasma), the logarithmic function (“pH,” normally 7.35 to 7.45 in plasma) is gener-

ally preferred both for convenience of representing a broad range of concentrations and because the free energy associated with changes in hydrogen concentration is related to the ratio rather than the difference between these concentrations:

$$\text{pH} = -\log_{10}[\text{H}^+] \quad [1]$$

or more precisely,

$$\text{pH} = -\log_{10}(a_{\text{H}^+}) \quad [2]$$

where (a_{H^+}) designates the “activity,” of H^+ . (a_{H^+}) is determined with a hydrogen ion electrode and numerically approaches the concentration of H^+ in dilute solutions. Although the concentrations of H^+ in tissue fluids are typically very low compared to those of electrolytes, they can be responsible for important free energy differences across cellular membranes if the ratio between compartmental concentrations is large. For example, much of the energy stored in mitochondria is attributable to the ratio of H^+ ion concentrations which is maintained across the inner membrane of the mitochondria (see later). Because the concentration of H^+ is routinely divided by the thermodynamic standard state activity of a solution containing 1 mole/L of H^+ ions, no units are used for a_{H^+} or pH.

Conjugate Acids and Bases

The *Brønsted-Lowry* (BL) concept has largely supplanted the Arrhenius and earlier approaches for describing acid-base reactions in chemical, physiologic, and clinical studies. By the BL criteria, an acid is a proton (H^+) donor, whereas a base is an H^+ acceptor. For example, BL acids are designated in roman font and BL bases in italics in the following reaction:

where CH_3COOH and CH_3COO^- represent the “conjugate acid-base pair” for acetic acid. CH_3COOH loses one H^+ when

the reaction proceeds to the right. H_3O^+ and H_2O represent the conjugate acid-base pair of water. H_2O accepts one H^+ as the reaction proceeds to the right.

Strong Versus Weak Ions

Ions that are completely ionized in water (e.g., Na^+ , K^+ , and Cl^-) are not considered as BL bases or acids because they neither accept nor donate H^+ ions, and they are sometimes referred to as “spectator ions.” Because the pH of the extracellular fluid is normally approximately 7.4, some interpretations of acid-base chemistry categorize many organic acids (with dissociation constants below ≈ 4.0 , see later) as “strong” acids because less than 0.1% of these acids remains undissociated in the extracellular milieu. Detection of excess concentrations of relatively strong anions such as lactate may indicate excessive intake, production, or retention of lactic acid. However, from the BL perspective, the corresponding lactate anion behaves as a weak base rather than an acid because lactate anions can accept H^+ ions. Furthermore, the presence of lactate anions may actually reflect infusions of solutions that promote alkalosis rather than acidosis. For example, an infusion of Ringer lactate initially dilutes the plasma, which tends to cause a dilutional acidosis (see later). However, subsequent metabolism of lactate to HCO_3^- results in alkalization.

Buffer Systems. Conjugate acid-base pairs can be used to minimize changes in pH when strong acids or bases (e.g., HCl and NaOH) are added to aqueous solutions. If the constituents of a solution are neither created nor destroyed and do not exchange with the environment, the system is referred to as “closed.” The effectiveness of a closed buffer system is maximal when the concentrations of the conjugate acids and bases are similar and exceed those of the strong acids or bases that are added, in other words, when the H_3O^+ of the solution is close to the dissociation constant (K_a) of the buffer pair. For a weak acid (HA):

where K_a is the acid-dissociation constant. Rearranging this equation and taking the logarithms of both sides yields the *generalized* Henderson-Hasselbalch equation:

$$\text{pH} = \text{p}K_a + \log \frac{[\text{A}^-]}{[\text{HA}]} = \text{p}K_a + \log \frac{[\text{base}]}{[\text{acid}]} \quad [4]$$

Buffering is maximal when $\text{pH} = \text{p}K_a$. It is usually assumed that concentrations of H^+ released from water are negligible compared to those derived from the acid.

Arterial pH is maintained at approximately 7.4, well above the $\text{p}K_a$ of $\text{HCO}_3^-/\text{PCO}_2$ buffer pair (6.1). This reflects the fact that this buffer pair is volatile and bicarbonate concentrations are kept at concentrations 20 times greater than those of dissolved carbon dioxide. Relatively high concentrations of HCO_3^- relative to those of carbon dioxide reflect in part a *steady state* relationship between the lungs and kidney that presumably consumes more energy than buffers maintained at *equilibrium*, but that allows this acid-base pair to efficiently neutralize nonvolatile acids produced in the body.

CARBON DIOXIDE AND BICARBONATE

By the early 20th century the importance of reactions of carbon dioxide and bicarbonate ion (HCO_3^-) with H^+ and OH^- in acid-base balance was well established¹:

reaction 6 provides the dominant pathway to HCO_3^- from carbon dioxide, but rates of formation of either H_2CO_3 (carbonic acid) in reaction 6 or HCO_3^- directly in reaction 5 are relatively slow in the absence of a catalyst. These rates are normally accelerated by *carbonic anhydrase* (CA) present in erythrocytes, vascular endothelium, alveolar epithelium, and in most other organs, including the kidney.²⁻⁴ Under physiologic conditions, $[\text{H}_2\text{CO}_3]$ is much less concentrated than $[\text{carbon dioxide}]$, and the relative amounts of HCO_3^- and carbon dioxide can be calculated from the *conventional* Henderson-Hasselbalch equation:

$$\text{pH} = \text{p}K_a + \log \frac{[\text{HCO}_3^-]}{\alpha \text{PCO}_2} \quad [7]$$

where the constant $\text{p}K_a$ ($= 6.1$ at 37°C) designates the negative logarithm of the apparent dissociation constant of carbon dioxide, which characterizes its equilibria with carbonic acid and the dissociation products in reaction 5 and 6. As noted earlier, $\text{p}K_a$ equals the pH when concentrations of HCO_3^- and dissolved carbon dioxide are equal. In [Equation 7](#), solute concentrations rather than activities are usually shown, and the dissolved carbon dioxide has been replaced by αPCO_2 , where α is the solubility coefficient, which is equal to 0.03 (mmol/L)/mm Hg at 37°C . The $\text{p}K_a$ and α remain relatively constant with clinical changes in pH and ionic strength⁵; however, they are significantly influenced by temperature. Fortunately, it is seldom necessary to correct pH for alterations in body temperature because of the manner in which the dissociation of constants of blood buffers (primarily imidazole groups in proteins) are affected by temperature.⁶ Some clinicians prefer to use the equation

$$\text{H}^+ = 24 \text{ PCO}_2 / [\text{HCO}_3^-] \quad [8]$$

where the units of H^+ , PCO_2 , and HCO_3^- are nanomoles/L, mm Hg, and mEq/L, and then convert calculated $[\text{H}^+]$ to pH.

MEASUREMENTS

PCO_2 and pH are readily measured with electrodes in arterial blood, but the pH detected is that in the plasma rather than in the red blood cells. Plasma pH is approximately 0.2 units greater than in red cells or in most other cells. The intracellular acid-base status of the body compartments is seldom measured; the plasma pH is often assumed to be representative of the body as a whole, and changes in plasma pH are assumed to reflect comparable changes within cells. This simplification is frequently inappropriate. For example, intracellular pH may be acidotic in patients with hypokalemia but who have an alkaline plasma. It is therefore more exact to refer to deviations from normal of plasma pH as *acidemia* and *alkalemia* rather than as acidosis and alkalosis. The latter terms refer to processes and do

not designate the actual pH or compartments. Intracellular pH is regulated by a complex array of transporters, and the pH of intracellular organelles can be extremely heterogeneous (as low as 4 to 5 in phagosomes and as high as 8 in nearby compartments of the mitochondria) (see Casey and associates⁷).

Plasma HCO_3^- is routinely calculated in the blood gas laboratory from measurements of arterial PCO_2 and pH using Equation 7. Alternatively, $[\text{HCO}_3^-]$ can be estimated from the total carbon dioxide that can be released from plasma with a strong acid (the *carbon dioxide content*). Carbon dioxide content is usually measured with electrolyte concentrations in venous blood and is usually approximately 5% higher than arterial HCO_3^- because it also includes H_2CO_3 , dissolved carbon dioxide, carbonate, and carbon dioxide bound to amino acids (carbamates) and because PCO_2 is higher in venous blood. If estimates of $[\text{HCO}_3^-]$ made from arterial and venous samples differ by more than 4 mEq/L, a variety of problems should be suspected, including very low cardiac output, clerical or technical errors, and collection at different times.

The pH and PCO_2 of blood are particularly likely to change if blood samples are exposed to air, if they are not kept cool, or if analysis is delayed. Exposure to air decreases PCO_2 , raises pH, and more gradually decreases carbon dioxide content. Fortunately, differences in carbon dioxide content of arterial and venous plasma are usually quite small, and venous samples can be used to provide reasonable estimates of the arterial HCO_3^- and directional changes in this parameter unless cardiac output is very low.

VENTILATORY PARAMETER: ARTERIAL PCO_2

The Henderson-Hasselbalch equation (Equation 7) indicates that pH can be calculated from two variables, PCO_2 and HCO_3^- , without consideration of other acid-base pairs in the plasma (isohydric principle). Arterial PCO_2 can be interpreted as a “ventilatory” parameter that reflects the adequacy of ventilation relative to the rate of carbon dioxide production. If arterial PCO_2 exceeds the normal range (35 to 45 mm Hg), then the patient is hypoventilating, and, conversely, if the arterial PCO_2 is lower, the patient is hyperventilating. These terms should be distinguished from hyperpnea and hypopnea, which refer to the increases or decreases of ventilation to meet respiratory requirements, as, for example, the hyperpnea during exercise, and from tachypnea and bradypnea, which indicate rapid and slow respiratory rates. Furthermore, the key parameter that determines arterial PCO_2 at any rate of carbon dioxide production is *alveolar* ventilation, because ventilation of dead space does not lead to the loss of carbon dioxide. Arterial PCO_2 is determined by the rate of carbon dioxide production, the ratio of the dead space to tidal volume, and minute ventilation.

The utility of arterial PCO_2 as a ventilatory parameter is readily illustrated by a few brief examples. Arterial PCO_2 is usually normal during moderate exercise, and the subject is neither hyperventilating nor hypoventilating, despite obvious hyperpnea and tachypnea. Patients with severe lung disease frequently hypoventilate despite both hyperpnea and tachypnea at rest, because much of the inhaled air is delivered to an enlarged physiologic dead space as a result of both shunting and regions of low \dot{V}_A/\dot{Q} ratio. An

increase in carbon dioxide production may be caused by an increased metabolic rate (e.g., exercise or fever) or occasionally by an acute release of carbon dioxide from HCO_3^- stores due to a severe, acute metabolic acidosis (e.g., during and after cardiopulmonary arrest or a grand mal seizure, when large amounts of lactic acid are produced and HCO_3^- is converted to carbon dioxide). Regardless of the reason that ventilation fails to keep pace with carbon dioxide production, the concomitant increase in arterial PCO_2 is classified as hypoventilation. Conversely, hyperventilation is frequently seen as a respiratory compensation for metabolic acidosis, or in response to hypoxia, anxiety, or other conditions that stimulate the carotid bodies and respiratory centers.

METABOLIC PARAMETERS

Titrimetry

Conceptually, the quantity of excess nonvolatile base or acid in samples of plasma or blood should be determined by titrating them to pH 7.4 with small volumes of a strong acid (HCl) or base (NaOH) in fully oxygenated samples kept at PCO_2 of 40 mm Hg and 37°C . It should be noted that when the PCO_2 is kept constant in the normal range, solutions of NaOH absorb carbon dioxide and are converted to solutions of NaHCO_3 , which can also be used to titrate acidic samples of plasma to pH 7.4. Titrimetry should in principal be used as the standard reference for all other methods of evaluating metabolic acidosis and metabolic alkalosis. It provides information regarding the concentration of acid or base in the plasma and the amount of HCl or NaOH that must be added to return the pH to 7.4. Unfortunately, titrimetry is difficult to perform, especially in blood, and it does not indicate which metabolic acids and bases are present. Three alternative metabolic parameters are currently in use: bicarbonate, base excess, and the strong ion difference.

Bicarbonate

Rather than laboriously titrating blood or plasma with strong acids and bases, measurements are usually made of plasma HCO_3^- to estimate the amount of nonvolatile acid or base that would be needed to restore pH_a to normal. Although it represents the oldest and most popular metabolic parameter, changes in plasma HCO_3^- underestimate the amount of acid (or base) that must actually be used to titrate samples of blood, plasma, or the body as a whole to a pH of 7.4. This reflects the presence of other buffer pairs that are also titrated by the strong acids and bases, which are generally nonvolatile and conserved (e.g., proteins and phosphates).

There is a second problem with using bicarbonate as a metabolic parameter: an ideal metabolic parameter should not be influenced by changes in arterial PCO_2 . As shown in Figure 7-1, in well-buffered solutions, HCO_3^- may increase significantly when arterial PCO_2 increases. If carbon dioxide is bubbled through a saline solution containing HCO_3^- without other buffers, the bicarbonate remains relatively constant over a broad range of PCO_2 . In contrast, when carbon dioxide is bubbled through samples of plasma or blood, HCO_3^- concentrations rise significantly, an effect due to the nonvolatile buffers available in plasma and blood (see Fig. 7-1, *in vitro* blood plot). As indicated in the reaction in

this figure, buffering by R^- can decrease concentrations of H^+ and promote formation of HCO_3^- (in accordance with the Le Chatelier principle.) The production of HCO_3^- from carbon dioxide in blood is increased when H^+ becomes associated with nonvolatile buffer anions (R^-) in the blood, which include hemoglobin, proteins, and inorganic phosphates. Red cell hemoglobin is particularly effective in buffering H^+ , for three reasons. First, the hemoglobin concentration is extremely high within red blood cells. Second, there is an abundance of titratable imidazole groups on the hemoglobin molecule, whose pK_a is very close to the pH within the cells and thus able to titrate large amounts of H^+ . Third, the buffering capacity of hemoglobin is nearly doubled by its oxylatable character (the Haldane effect) so that, at low PO_2 values, such as those encountered in systemic capillaries and venous blood, its affinity for H^+ is increased, allowing

Figure 7-1 The relation between PCO_2 and HCO_3^- in samples of isotonic saline with 25 mEq/L $NaHCO_3$ (unbuffered solution), in samples of whole blood (in vitro), and in samples of arterial blood drawn from patients 20 minutes after exposure to elevations of PCO_2 (in vivo).

more carbon dioxide conversion to HCO_3^- . At high PO_2 values, such as those encountered in the pulmonary capillaries, the affinity for H^+ is reduced, HCO_3^- is converted to carbon dioxide, and the carbon dioxide is removed from the lungs by ventilation.

Base Excess

The reliability of plasma HCO_3^- as a metabolic parameter has been challenged because the proteins and phosphate buffers in plasma and blood promote increases in $[HCO_3^-]$ when samples of plasma or blood are exposed to high carbon dioxide tensions. This led to the development of alternative approaches that use other parameters that are relatively independent of PCO_2 . Among many schemes devised for this purpose, mention should be made of the HCO_3^- -pH graphs of Davenport⁸ and the concepts of buffer base and base excess of Astrup and Sigaard-Anderson.⁹ The base excess estimates how much strong acid or alkali must be added to titrate fully oxygenated blood to a pH of 7.4 at 37°C and at the hemoglobin concentration in that sample.

Although the base excess can accurately predict the in vitro changes in the pH of samples of blood after addition of acid or base or exposure to high or low PCO_2 , it is less reliable in predicting the in vivo changes of pH when blood samples are collected from patients who are exposed to metabolic and respiratory challenges. When the in vivo response of HCO_3^- to an acute change in arterial carbon dioxide tensions (arterial PCO_2) was determined empirically in normal subjects, it was found that increases in arterial PCO_2 from 40 to 78 mm Hg resulted in arterial plasma HCO_3^- increases of only 3 mEq/L.¹⁰ The range of HCO_3^- that would be expected in 95% of samples obtained in a normal population after acute increases in arterial PCO_2 is indicated in the acute respiratory acidosis band in Figure 7-2A. This graph also indicates (in the acute respiratory alkalosis band) that there is a tendency for HCO_3^- to fall somewhat

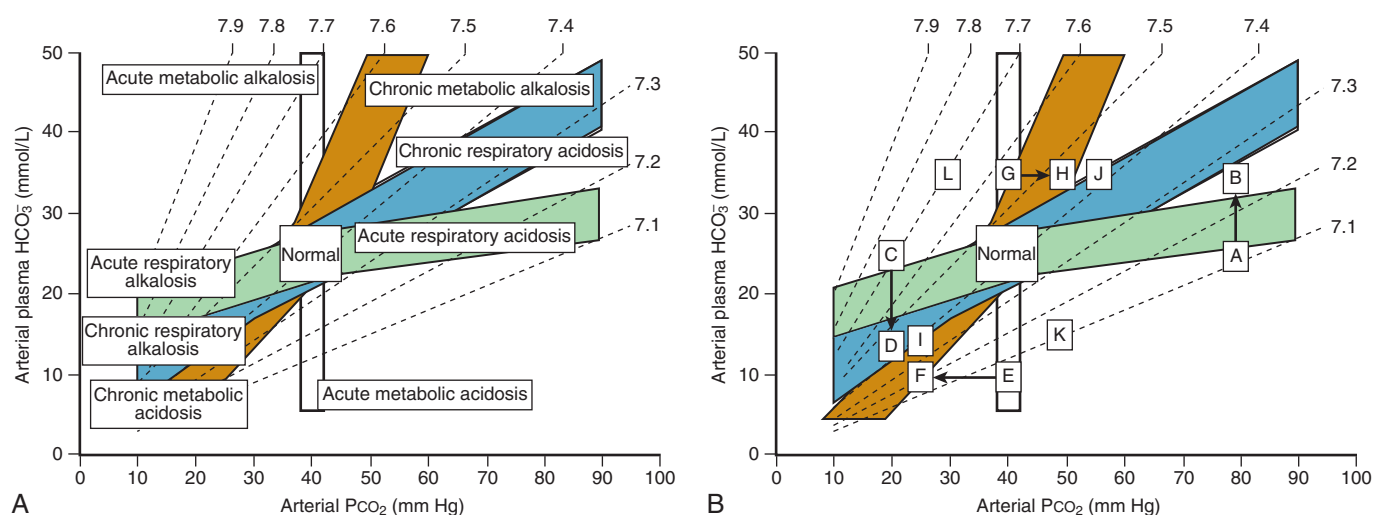

Figure 7-2 The relation between HCO_3^- and PCO_2 in a variety of clinical disorders. For discussion, see text. **A**, The 95% confidence levels for acute and chronic respiratory and metabolic abnormalities. **B**, The interpretation of examples in Table 7-1 is based on the assumption that PCO_2 is a purely respiratory parameter and HCO_3^- is a purely metabolic parameter. The vertical, colorless bar indicates the absence of any change in arterial PCO_2 with acute changes in bicarbonate. However, the respiratory response to the onset of metabolic acidosis and alkalosis is rapid, and the metabolic band rotates clockwise toward the chronic metabolic position within a matter of minutes to hours. Compensatory metabolic responses to respiratory changes in arterial PCO_2 are much slower, making it easier to observe the acute respiratory bands before metabolic compensation.

more with decreases in arterial PCO_2 than to rise with increases in arterial PCO_2 .^{11,12} This is due in part to a slight increase in lactate in patients who are hyperventilating, which in turn may be due to an alkalosis-mediated increase in the activity of the enzyme phosphofructokinase (see later discussion). Recognition that increases in arterial PCO_2 in vivo result in smaller increases in base excess in patients than those observed in vitro led to the somewhat arbitrary practice of assuming that the nonbicarbonate buffering of the extracellular fluid is equivalent to an “anemic” sample of blood that has been diluted threefold or contains only 50 g/L hemoglobin. (These assumptions could obviously be misleading if the patient is very edematous or anemic.) This revised metabolic parameter is usually referred to as the “standard base excess” and normally varies between -2 and $+2$ mEq/L. A further corrected form of the standard base excess incorporates plasma concentrations of both albumin and phosphate (SBEc).¹³

The relative stability of HCO_3^- in the face of acute changes in arterial PCO_2 is responsible for much of the popularity of HCO_3^- as a useful, though approximate, metabolic parameter and for the gradual decline in the use of the buffer base and base excess systems for diagnostic purposes. Regardless of which metabolic parameter is used, it must ultimately be validated with empirical observations made in subjects who are intentionally hyperventilated or hypoventilated (see Fig. 7-2). Of course, the assumption that the same criteria and normograms should apply to all patients, regardless of age, gender, or other characteristics, is unrealistic. It should also be emphasized that immediately after exposure to elevated alveolar carbon dioxide tensions in the alveoli, the HCO_3^- concentrations in the plasma within pulmonary capillaries and veins and then within the systemic arteries should increase in a manner similar to that observed in vitro. However, arterial HCO_3^- concentrations rapidly fall from peak values as carbon dioxide and HCO_3^- diffuse into the tissues and as the buffering capacity of conserved buffers (primarily proteins) in the blood is exhausted. Both the bicarbonate and standard base excess measurements are conveniently made in samples of whole blood at the same time that pH, PCO_2 , and PO_2 and hemoglobin concentration and saturation as well as carboxyhemoglobin and methemoglobin concentrations can be evaluated in the arterial blood gas laboratory.

Strong Ion Difference

Stewart¹⁴ and subsequently Constable^{15,16} endeavored to analyze acid-base disorders on the basis of the concentrations and dissociation constants of each of the strong and weak acids and bases present in the plasma, thereby avoiding either titration or the use of some of the approximations associated with earlier approaches. They modified a method that has long been used by chemists to estimate the effect of multiple acids and bases on arterial pH. Stewart¹⁴ and Constable^{15,16} calculated the arterial plasma pH and HCO_3^- from (1) the difference between total concentrations of strong cations and strong anions in the plasma (*strong ion difference* [SID], which is normally 40 to 42 mEq/L), (2) the total concentration and dissociation constants of all nonvolatile weak acids and bases (primarily albumin and phosphates), and (3) the PCO_2 . The SID is normally close to the difference between Na^+ and Cl^- concentrations, and albumin

usually accounts for much of the weak nonbicarbonate anions in the SID. Stewart assumed that all of the constituents in the plasma other than H^+ , carbon dioxide, HCO_3^- , and CO_3^{2-} were conserved and that the solution remained electroneutral. Furthermore, he included organic anions such as lactic acid with pK_a below 4 among the “strong” ions because these molecules are largely ionized at physiologic pH. The simultaneous equations for pH and HCO_3^- were then solved iteratively as a fourth-order polynomial using a computer program. Stewart concluded that “metabolic” changes in acid-base balance are due to alterations in either SID or the total concentration. If serum albumin concentrations are normal, then an increase in SID indicates a metabolic alkalosis and a decrease in SID indicates a metabolic acidosis.

In principle there is merit in defining the effects of each of the acid-base pairs upon the plasma pH. However, it is difficult to make sufficiently precise measurements of the constituents of the SID and the concentrations of weak acids and bases in the plasma, many of which have not been identified or properly quantified, especially in patients with liver or kidney disease.^{17,18} Furthermore, the assumption that a single dissociation constant can be assumed for all of the weak acids is questionable. Stewart’s distinctions between “independent” and “dependent” variables as well as his assumption that H^+ and HCO_3^- transport do not alter compartmental pH have also been challenged.¹⁹⁻²¹ Nor does the SID approach distinguish between acute and chronic disorders. The original suggestion that pH and HCO_3^- can be calculated rather than measured is particularly unfortunate because these two variables can be much more easily and reliably measured than indirectly estimated from concentrations of all of the nonvolatile acids and bases in the blood.

It can be concluded that none of the three most popular metabolic parameters (bicarbonate, base excess, and strong ion difference) provides a completely reliable estimate of the quantity of nonvolatile H^+ or OH^- that has been added to the blood or plasma samples, as judged by actually titrating the samples. Nor is it clear that either in vitro titration or SID calculations would provide a reliable guide to the in vivo acid-base status of patients. Consequently, frequent monitoring of arterial blood is essential in patients with metabolic acid-base disorders who are receiving infusions of acidic or alkaline fluids.

In conclusion, it remains unproven that any of the alternative approaches yields more reliable information than the conventional practice of using PCO_2 as a respiratory parameter, bicarbonate as a metabolic parameter, and the “anion gap” to interpret the effects of changes in concentrations of nonvolatile constituents in the blood (see later). The conventional approach will therefore be retained in the remainder of this chapter.

ROLE OF THE KIDNEYS

Approximately 1 mEq/kg of “fixed” acids (i.e., acids other than H_2CO_3) are produced daily in the metabolism of a typical protein diet.^{22,23} These nonvolatile acids cannot be excreted by the lungs and must be removed from the body by other routes, or buffered, to avoid progressive acidosis. Both sulfate and phosphate are produced, and these may be

accompanied by a variety of organic acids, some of which escape metabolism and contribute to the daily acid load. Successful excretion of these ions by the kidneys depends on both tubular H^+ transport and the presence of urinary buffers. In the absence of buffers, less than 0.1 mEq of acid per liter would be excreted even at the lowest urinary pH (4.5) generated by the kidneys.

The three most important buffers found in urine are bicarbonate/carbon dioxide, ammonium/ammonia, and titratable acids. Approximately 3600 mEq of HCO_3^- are filtered through the glomeruli daily, but losses in the urine are trivial. Most of the filtered HCO_3^- is reclaimed by an exchange of intracellular H^+ for Na^+ (through a Na^+-H^+ antiporter, NHE3) rather than by direct HCO_3^- reabsorption, although the latter process may be stimulated in acidotic states. Intracellular H^+ generation is mediated by hydration of carbon dioxide to H_2CO_3 , which is enhanced by carbonic anhydrase and is followed by the dissociation of H_2CO_3 to H^+ and HCO_3^- . H^+ entering the proximal tubule combines with HCO_3^- and rapidly regenerates carbon dioxide and H_2O , accelerated by the presence of carbonic anhydrase (types IV and XIV) on the luminal surface of the proximal tubule cells. The HCO_3^- formed within proximal tubule cells moves across the basolateral membranes in exchange for chloride through channels facilitated by basolateral membrane carbonic anhydrase (type XII).

Removal of HCO_3^- from proximal tubular fluid is essential, and failure to do so inevitably leads to hyperchloremic acidosis. However, HCO_3^- reabsorption does not result in acid excretion in the urine and therefore cannot contribute to fixed acid excretion. Unlike HCO_3^- , which is usually reabsorbed by the nephrons, titratable acids and ammonium reach the urine, and most H^+ is carried into the urine by these buffers. The principal titratable anion is $H_2PO_4^-$, most of which is secreted into the proximal tubule. During ketoacidosis, β -hydroxybutyric acid also can act as an effective buffer.

NH_4^+ is produced from glutamine by the proximal tubular cells, and this process can be stimulated by chronic acidosis, which increases glutamine uptake through H^+ -dependent glutamine transporters on the proximal tubular cells. NH_4^+ is secreted into the proximal tubule through a *sodium-hydrogen exchanger* (NHE3). Some of this ion is reabsorbed in the thick ascending limb of the tubule, and a fraction is converted into NH_3 . This increases medullary concentration of NH_3 , which diffuses into the collecting ducts. Because the collecting duct fluid tends to be very acidic, NH_3 becomes “trapped” as NH_4^+ . Details regarding renal metabolism and excretion of NH_3 and NH_4^+ can be found elsewhere.^{22,23}

Movement of H^+ into the proximal nephron differs in a number of important respects from transport in the distal nephron. Because the proximal tubule is responsible for absorbing most of the filtered HCO_3^- , considerably more H^+ is transported at this location than distally (≈ 3600 mEq, as described earlier, versus 50 to 100 mEq of fixed acids). However, the ability of the proximal tubule to concentrate H^+ is limited, and the fluid leaving the proximal tubule has a pH of approximately 6.8. Although the more distal portions of the tubule secrete less total H^+ than the proximal tubules, they increase H^+ concentration by almost 1000-fold compared with plasma, producing a urinary pH as low as 4.5. This permits net renal excretion of the acids

normally generated by metabolism. Distal tubular acid secretion is mediated by a vacuolar H^+ -ATPase and K^+/H^+ -ATPase on the luminal surface of the alpha intercalated cells of the collecting tubules and by transporters on inner medullary cells. This process is accelerated by electrogenic Na^+ reabsorption by adjacent principal cells, a process that makes the electrical potential of the tubular lumen more negative and thereby enhances secretion of H^+ . When alkalosis is present, a second population of intercalated cells designated as beta cells secretes HCO_3^- into the distal tubules.

Because carbon dioxide readily diffuses across cell membranes, the PCO_2 and pH of the renal tubular cells are affected promptly by changes in arterial PCO_2 . These changes initiate changes in renal H^+ excretion, with an increase during hypercapnia and decrease during hypocapnia.

NOMENCLATURE OF ACID-BASE DISORDERS

Procedures for naming acid-base disorders become quite simple if carbon dioxide and HCO_3^- are used as the respiratory and metabolic parameters. An additional assumption is made that compensation is incomplete. If arterial pH is low, the primary disorder must be an acidosis, and, if high, the primary disorder is an alkalosis. A secondary or compensatory change in either the respiratory or the metabolic parameter restores pH toward normal, but this effect should remain incomplete. On the basis of this approach, abnormal combinations of pH, PCO_2 , and HCO_3^- can be designated in terms of a primary disorder and any compensation that might be present.

Examples of virtually every combination of primary and secondary changes are provided in Table 7-1 and illustrated in Figure 7-2. Figure 7-2A indicates the ranges in which HCO_3^- and PCO_2 changes have been observed in normal persons subjected to acute or chronic respiratory or metabolic changes. Figures 7-2A and B are based on the simple assumption that HCO_3^- changes reflect metabolic events, whereas changes in PCO_2 reflect respiratory events (as indicated in Table 7-1). Some comments concerning the reliability of this preliminary analysis are provided in Table 7-1 and are discussed later in the chapter. Horizontal deviations on these coordinates indicate respiratory changes, whereas vertical deviations designate metabolic changes. Four primary disorders (A, C, E, and G) and four compensatory responses (B, D, F, and H) are shown in Figure 7-2. Each of the latter responses returns the pH toward 7.4. However, the pH remains abnormal in the same direction as the primary change. Note that if respiratory and metabolic parameters change proportionately, pH does not change and, in this case, remains normal (I and J). In this circumstance the disorder is considered a “mixed” combination of primary disorders. Another mixed disorder arises when both parameters are altered in a fashion that changes the pH in the same direction (K and L) and neither change can be considered as compensatory. A third type of mixed disorder must be entertained if a patient simply fails to “compensate” in the expected manner for a primary disorder after sufficient time has elapsed, perhaps indicating a failure of renal or pulmonary function.

Because the three variables must be related by Equation 3, not all combinations of pH, PCO_2 , and HCO_3^- are possible. One combination (M), which is chemically impossible and

Table 7-1 Laboratory Classification of Acid-Base Disorders

Location in Figure 7-2	Metabolic Parameter HCO_3^- (mEq/L)	pH	Respiratory Parameter PCO_2 (mm Hg)	Preliminary Interpretation	Comments Based on Bands (Fig. 7-2)
Normal range	23-27	7.35-7.45	38-42		
A	25	7.12	80	Respiratory acidosis	A small increase in (uncompensated) HCO_3^- is usually seen with acute respiratory acidosis
B	35	7.25	80	Respiratory acidosis (compensated)	Compensation has not reached expected confidence levels
C	25	7.71	20	Respiratory alkalosis (uncompensated)	A decrease in HCO_3^- would be expected; acute respiratory alkalosis
D	15	7.50	20	Respiratory alkalosis (compensated)	Compensation exceeded expected range
E	10	7.03	40	Metabolic acidosis (uncompensated)	A completely uncompensated metabolic acidosis should be very transient if the ventilatory response is normal
F	10	7.23	25	Metabolic acidosis (compensated)	Compensation is nearly maximal
G	35	7.56	40	Metabolic alkalosis (uncompensated)	
H	35	7.46	50	Metabolic alkalosis (compensated)	Compensation is in expected range
I	16	7.40	25	Metabolic acidosis and respiratory alkalosis	Mixed disorder
J	35	7.40	56	Metabolic alkalosis and respiratory acidosis	Mixed disorder
K	15	7.10	50	Metabolic acidosis and respiratory acidosis	Mixed disorder
L	35	7.67	30	Metabolic alkalosis and respiratory alkalosis	Mixed disorder
M	15	7.30	60	Laboratory error	

Interpretation based on assumption that PCO_2 is a respiratory parameter and HCO_3^- is a metabolic parameter.

cannot be plotted, must represent a laboratory error or timing differences at which various parameters were obtained, is indicated in Table 7-1. “Triple disorders” may also be encountered, involving a mixture of two or more independent processes that induce metabolic acidosis (detected by abnormal anions) in the presence of a respiratory disorder. Measurement of additional anions in plasma may permit identification of even more complex disorders. However, it is obviously not possible to have both hyperventilation and hypoventilation at the same time.

Several caveats should be heeded regarding both this and other systems that classify acid-base disorders strictly on the basis of pH, PCO_2 , and a metabolic parameter. Distinction between primary and compensatory disorders in the laboratory is based simply on which alteration is proportionately greater at the time the blood was drawn rather than on the sequence of events involved. For example, it is common for patients with *chronic obstructive pulmonary disease* (COPD) to be admitted to the hospital with compensated respiratory acidosis. With therapy the PCO_2 may decrease, leaving what might otherwise in the absence of the clinical history be taken as “a primary metabolic alkalosis with secondary respiratory compensation.” Winters²⁴ suggested that a distinction be made between the “physiologic” language commonly used by the physician and the “laboratory” terminology that is strictly based on blood parameters.

Laboratory definitions of primary and secondary or compensatory alterations of acid-base disorders assume that one is greater than the other and that there has been sufficient time for compensatory processes to reach their full quantitative expression. As discussed later, complete respiratory compensation takes hours, but full renal compensation takes several days. Thus, in any rapidly evolving and changing disease scenarios, clinicians should not always assume that lack of an expected compensation mandates consideration of a second or third primary disorder. Under some circumstances, however, compensation (correction to normal pH) may be complete in the apparent absence of what could be identified as a second primary disorder. For example, full compensation is observed among COPD patients who are chronically hypercapnic, whose lung function can improve over the course of the day with clearance of secretions. With better ventilation and \dot{V}_A/\dot{Q} matching, arterial PCO_2 falls and pH increases to normal or even higher than normal levels before the kidneys can quantitatively respond (see later discussion on [compensations](#)). Full compensation is also characteristic of the chronic hyperventilation observed at high altitude.

If HCO_3^- were a strictly metabolic (“nonrespiratory”) variable, then changes in PCO_2 would result in movement along a line perpendicular to the HCO_3^- axis (e.g., A and C in Fig. 7-2B). The actual response of HCO_3^- to acute and chronic changes can be indicated by the 95% confidence bands

Table 7-2 Rules of Chronic Compensation

Primary Disorder	Secondary Compensation	EXAMPLES	
		Primary Change	Compensation
↑ PCO ₂	↑ HCO ₃ ⁻ : 4 mEq/L for each 10-mm Hg increase in PCO ₂ (±3 mEq/L)	PCO ₂ : 40 → 80	HCO ₃ ⁻ : 24 → 40 pH: 7.1 → 7.32
↓ PCO ₂	↓ HCO ₃ ⁻ : 2.5 mEq/L for each 10-mm Hg decrease in PCO ₂ (±3 mEq/L)*	PCO ₂ : 40 → 20	HCO ₃ ⁻ : 24 → 19 pH: 7.70 → 7.60
↓ HCO ₃ ⁻	↓ PCO ₂ : 1–1.5 mm Hg for each mEq/L decrease in HCO ₃ ⁻	HCO ₃ ⁻ : 24 → 9	PCO ₂ : 40 → 25 pH: 7.00 → 7.20
↑ HCO ₃ ⁻	↑ PCO ₂ : 0.5–1.0 mm Hg for each mEq/L increase in HCO ₃ ⁻	HCO ₃ ⁻ : 24 → 34	PCO ₂ : 40 → 50 pH: 7.56 → 7.46

*HCO₃⁻ seldom falls below 18 mEq/L in acute and 16 mEq/L in chronic respiratory alkalosis.

shown in Figure 7-2. Note that both A and C deviate from the expected responses to acute changes in PCO₂ (see comments in Table 7-1). Because PCO₂ is assumed to be a reliable index variable of ventilation, E and G represent metabolic changes without respiratory compensation.

COMPENSATIONS

Respiratory Acidosis

Although the acute increase in HCO₃⁻ is relatively modest after onset of hypercapnia, HCO₃⁻ continues to rise if hypercapnia persists and reaches a peak value after approximately 5 days (Table 7-2). This is related primarily to an increase in the exchange of H⁺ for Na⁺ in the proximal tubule and increased HCO₃⁻ reabsorption (see later discussion). Increases in plasma HCO₃⁻ require an initial net loss of H⁺, which is made possible by the loss of increased quantities of NH₄⁺ in the urine. Once plasma HCO₃⁻ has reached a new steady state, H⁺ secretion need only be sufficient to reabsorb HCO₃⁻ from the tubular fluid, and NH₄⁺ and H⁺ excretion usually return to normal. In contrast, excretion of both net NH₄⁺ and net H⁺ remains elevated in chronic metabolic acidosis, because the daily load of nonvolatile acids must be excreted, over and above the acid excretion needed for reabsorption of HCO₃⁻. Differences in NH₄⁺ and net H⁺ excretion in chronic respiratory and metabolic acidosis may be related to the fact that proximal tubular fluid contains high concentrations of HCO₃⁻ in chronic respiratory acidosis but low concentrations are present in chronic metabolic acidosis. Increased HCO₃⁻ flux into the proximal tubular cells in chronic respiratory acidosis keeps intracellular pH relatively alkaline compared with the situation observed in chronic metabolic acidosis. Intracellular acidosis stimulates secretion of NH₄⁺ in chronic metabolic acidosis.²⁵

Respiratory Alkalosis

Hypocapnia results in a decrease in renal acid excretion and a fall in HCO₃⁻ that becomes fully evident within 2 to 3 days. As indicated in Table 7-2, HCO₃⁻ decreases by 2.5 mEq/L for each decrease of 10 mm Hg in PCO₂²⁶ and does not generally fall much below 16 mEq/L in respiratory alkalosis unless there is an independent metabolic acidosis present. In contrast, an increase of approximately 4 mEq/L of HCO₃⁻ may be expected when PCO₂ is increased in steps of

10 mm Hg. Confidence bands for chronic compensation are indicated in Figure 7-2A.

Metabolic Acidosis

Respiratory compensation for metabolic disorders is quite fast (within minutes) and reaches maximal values within 24 hours. A decrease in PCO₂ of 1 to 1.5 mm Hg should be observed for each mEq/L decrease of HCO₃⁻ in metabolic acidosis.²⁷ A simple rule for deciding whether the fall in PCO₂ is appropriate for the degree of metabolic acidosis is that the PCO₂ should be equal to the last two digits of the pH. For example, compensation is adequate if the PCO₂ decreases to 28 when the pH is 7.28. Alternatively, the PCO₂ can be predicted by adding 15 to the observed HCO₃⁻ (down to a value of 12). Although reduction in PCO₂ plays an important role in correcting any metabolic acidosis, evidence suggests that it may in some respects be counterproductive because it inhibits renal acid excretion.

Metabolic Alkalosis

Compensation for metabolic alkalosis results in a decrease of ventilation and a rise of PCO₂ by approximately 0.6 to 0.7 mm Hg for each mEq/L increase in HCO₃⁻, but it seldom results in a PCO₂ much greater than 55 mm Hg²⁸ because the accompanying hypoxemia from hypoventilation generates an opposing ventilatory stimulus. Furthermore, compensatory increases in PCO₂ may be more pronounced in patients with metabolic alkalosis who have not lost K⁺. Losses of K⁺ are associated with an intracellular rise in H⁺, including the neurons of the respiratory center.²⁸ A variety of other factors have been reported that can increase PCO₂ values in patients with metabolic alkalosis.²⁹ Respiratory compensation for metabolic alkalosis, like that for metabolic acidosis, can have a counterproductive effect on renal H⁺ transport: increases in PCO₂ associated with metabolic alkalosis decrease intracellular pH in the kidney, thereby promoting acid secretion and further increasing serum HCO₃⁻ levels.³⁰

METABOLIC ACIDOSIS

ANION GAP CONCEPT

The most useful classification of metabolic acidosis is based on the concept of the anion gap, which is calculated by

Figure 7-3 Typical anion gap (AG) profiles are shown for eight different acid-base conditions (see text). Because these histograms do not show pH, $[H^+]$, or PCO_2 , they do not indicate whether acidemia or alkalemia are present, but they do provide useful information about the nature of these disorders. The value of the AG is shown above each bar, and the bicarbonate concentrations are indicated (mEq/L). **A**, Normal. **B**, Anion gap acidosis. **C**, Hyperchloremic acidosis. **D**, Primary metabolic alkalosis. **E**, Compensated respiratory acidosis. **F**, Excess cations other than Na^+ creating a cation gap (CG). **G**, Contraction alkalosis. **H**, Dilutional acidosis.

subtracting the sum of plasma concentrations of Cl^- and HCO_3^- from that of Na^+ (Fig. 7-3). This difference, which uses fewer ion concentrations than the strong ion difference, provides a convenient index of the relative concentrations of plasma anions other than Cl^- and HCO_3^- . Normally the anion gap is between 8 and 16 mEq/L, although somewhat lower values (5 to 11 mEq/L) have been observed when newer techniques for measuring ion activities rather than total concentrations are used.³¹⁻³³ Among other anions present in plasma are albumin (with multiple anionic groups at physiologic pH that normally constitute approximately half of the gap), lactate, pyruvate, sulfate, and phosphate. Elevations of the anion gap usually indicate accumulation of some acid other than HCl in the plasma and are generally accompanied by a similar decrease in HCO_3^- ("anion gap acidosis") (see B in Fig. 7-3). Alternatively, reduction in $[HCO_3^-]$ may be caused by an increase in $[Cl^-]$ without an increase in the anion gap (hyperchloremic acidosis) (see C in Fig. 7-3).

Appropriate application of the anion gap approach requires appreciation of a number of factors:

1. Although addition of acids other than H_2CO_3 and HCl to plasma tends to increase the anion gap, this effect is somewhat less than might be expected, because H^+ tends to combine with negative groups on the albumin molecules, thereby reducing the contribution of this protein to the anion gap. In contrast, alkalemia tends to increase the number of anionic groups on albumin, thereby increasing the anion gap. Recognition of this phenomenon may be helpful when high HCO_3^- concentrations

are reported with electrolytes in the venous blood but arterial pH and PCO_2 are unavailable. For example, if an elevated HCO_3^- is related to a primary metabolic alkalosis (see Fig. 7-3D), the blood is alkaline and hydrogen ions are removed from albumin and other buffers. The anion gap will consequently be increased (e.g., 15 mEq/L). On the other hand, if the elevation in HCO_3^- is due to respiratory acidosis with a secondary increase in reabsorption of HCO_3^- from the renal tubules, the primary acidemia will tend to reduce the anion gap (e.g., 5 mEq/L) (see Fig. 7-3E).

2. Because approximately half of the anion gap is normally related to negative charges on albumin, hypoalbuminemia decreases the anion gap by approximately 2.5 mEq/L for each decrease in albumin concentration of 1 g/dL.³²
3. A low anion gap, which may be less than zero, may reflect an increase in cations other than Na^+ (e.g., calcium $[Ca^{2+}]$, magnesium $[Mg^{2+}]$, lithium $[Li^+]$, and abnormal cationic proteins in multiple myeloma). As illustrated in Figure 7-3F, the anion gap may be low or even negative, because of an increase in the concentration of unknown cations. This can be considered as a negative anion gap or a positive cation gap.
4. Losses of water during dehydration increase the levels of all solute concentrations, including bicarbonate and the anion gap (see Fig. 7-3G). Because the respiratory center keeps PCO_2 relatively constant compared to HCO_3^- , metabolic alkalosis may ensue. Retention of water (or saline), has the opposite effect, reducing HCO_3^- relative to PCO_2 , thereby promoting a "dilutional acidosis" (see Fig. 7-3H).

5. Administration of large quantities of sodium salts of anionic antibiotics (e.g., penicillin and related drugs) or other anions (e.g., lactate, citrate, acetate) can also increase the anionic gap without acidosis. If anions of this type have not been administered and the patient is not dehydrated, then an increased anion gap suggests an underlying metabolic acidosis, even if the pH is normal or high.
6. Because much of the H^+ produced in the body is buffered by non- HCO_3^- buffers within cells, the decrease in HCO_3^- tends to be less than the increase in the anion gap when metabolic acidosis is present. For example, the increase in the anion gap averages approximately 60% more than the decrease of HCO_3^- in lactic acidosis. Because ketones are more readily lost in the urine than lactate, the increase in the anion gap is generally similar to the decrease in HCO_3^- in conditions that result in ketoacidosis³³ (see later discussion). Conversely, if the decrease in HCO_3^- exceeds the increase in the anion gap, it is likely that at least part of the acidosis is caused by a non-anion gap hyperchloremic acidosis.

ANION GAP ACIDOSIS^{33a}

Lactic Acidosis

Approximately 1400 mEq of lactate are normally produced each day,³⁴ but production can increase by an order of magnitude in heavy exercise. At rest, production is balanced by consumption and precisely regulated so that serum levels are kept at approximately 1 mEq/L. Most lactate is produced by the skeletal muscles, but with various stresses such as ischemia, profound hypoxemia, sepsis, and high sympathetic tone, other tissues may also generate lactate. In resting healthy individuals, the liver and, to a lesser extent, the kidneys are responsible for most of its consumption,³⁴ with oxidation in red skeletal muscle accounting for the remainder. Although lactate is the main gluconeogenic precursor in liver and kidneys during physical exertion, oxidation in working muscle accounts for 70% to 80% of lactate disposal. Newer work and analysis of glycolytic intermediary metabolism suggest that we may have to reconsider our classic thinking about what we have long termed “lactic acidosis.” From a strict biochemical standpoint, it is lactate and not lactic acid that is generated at the terminal point in glycolysis when pyruvate is reduced to lactate by lactate dehydrogenase, a step that consumes rather than produces a proton (Fig. 7-4).

In terms of proton production, analysis of the glycolytic pathway shows the pathway to be proton neutral. Thus the acidosis that develops when lactate rises with exercise and possibly with other conditions associated with lactate accumulation and acidosis may be misleading.³⁵ It has been suggested, in fact, that if there were no lactate formation, the degree of acidosis arising in these circumstances would even be greater. The hydrogen ion that is formed in states of “lactic acidosis” arises from *adenosine triphosphate* (ATP), whose hydrolysis generates a hydrogen ion.

Under conditions where *adenosine diphosphate* (ADP) is not rephosphorylated, H^+ will accumulate. This occurs with true oxygen deficiency in ischemic (severe hypoperfusion) or very hypoxemic states when oxygen delivery cannot be maintained to support aerobic metabolism. Although the production of excessive quantities of lactate is thought to be linked in some way to tissue hypoxia in many clinical conditions associated with lactic acidosis, there has been little evidence of tissue hypoxia in maximally exercising muscle³⁶ or in sepsis,³⁷ though it would be difficult to detect small local regions of tissue hypoxia. The benign, or rather efficacious, nature of lactate has been demonstrated in “lactate clamp” studies,³⁸ in which lactate concentration is raised to 4 mM by infusion of a sodium lactate–lactic acid mixture along with glucose and lactate tracers. Under these conditions, lactate is the preferred fuel, and, because its disposal via gluconeogenesis or oxidation involves proton removal, lactate infusions have a mild alkalinizing effect. Nevertheless, the increase in lactate and production of acid during heavy exercise is presumably attributable to an increase in the fraction of glucose diverted to glycolytic rather than mitochondrial metabolism.

As indicated in Figure 7-4, glucose is normally metabolized to pyruvate, which is in equilibrium with lactate, at a ratio of 1:10 at rest and rising to 1:100 with exercise. Lactate can be metabolized only if it is converted back to pyruvate either in the cytosol or in the mitochondria (see later discussion). Pyruvate can be transported into the mitochondria in either of two ways. In gluconeogenic organs, carbon dioxide can be added to pyruvate by the enzyme pyruvate carboxylase to form oxaloacetate, which can then be converted to phosphoenolpyruvate and converted to glucose-6-phosphate and glucose. Alternatively, pyruvate can be oxidized to acetyl coenzyme A (CoA) by pyruvate dehydrogenase. Acetyl CoA then combines with oxaloacetate and is metabolized to form both ATP and *nicotinamide adenine dinucleotide* (NAD^+). In the absence of sufficient oxygen, *nicotinamide adenine dinucleotide*, reduced ($NADH$) cannot be oxidized to NAD^+ , and ATP production by the cytochrome system is blocked. Because the carboxylase reaction requires ATP and the dehydrogenase reaction requires NAD^+ , pyruvate can no longer enter the mitochondria, and concentrations of both cytosolic pyruvate and lactate increase. Increased cytosolic $NADH$ results in a disproportionate lactate increase. In addition, accumulation of cytosolic ADP, adenosine monophosphate, and phosphates activates phosphofructokinase and pyruvate kinase. This in turn increases metabolism of glycogen and glucose, which are effectively converted to lactate, a sequence of events referred to as the “Pasteur effect.” In effect, hypoxia promotes lactic acidosis both by increasing lactate production and by reducing its metabolism (see Fig. 7-4).

Lactate concentrations over 4 mM are associated with high mortality in most disease states. Increased lactate:pyruvate ratios may indicate the presence of tissue hypoxia, but it is difficult to measure pyruvate concentrations, especially when lactate levels are elevated. Venous concentrations are close to arterial, but it may be preferable to collect blood from the pulmonary artery or systemic arteries to be sure that the values represent an average of the body as a whole rather than from one extremity.

As mentioned previously, in many supposedly hypoxic tissue states, such as heavy exercise, seizures, and sepsis, oxygen delivery is not necessarily insufficient, and other causes for increased lactate formation and acidosis must be considered. One important cause is heightened sympathetic activation and catecholamine stimulation of glycolysis in excess of mitochondrial capacity for pyruvate uptake and metabolism arising from stimulated membrane ATP utilization by Na^+/K^+ -ATPase and accumulation of ADP, H^+ , and phosphate.³⁷ It has been suggested that lactate itself can enter the mitochondria in what has been termed the “intracellular lactate shuttle” under conditions in which pyruvate entry for reasons not entirely known may be insufficient by the classic entry pathways.^{38,39} Mitochondrial lactate entry is facilitated by a monocarboxylic transporter–lactate dehy-

Considering the marked arterial hypoxemia in some patients with severe respiratory insufficiency or cyanotic

heart diseases, it may seem paradoxical that lactic acidemia is not observed more frequently. Lactic acidosis is much more likely to appear when tissue perfusion is impaired than when arterial P_{O_2} is moderately reduced. Several compensations for chronic arterial hypoxemia help minimize tissue hypoxia: cardiac output rises, the hematocrit rises, and, if pH declines in those with carbon dioxide retention, hemoglobin oxygen affinity falls because of increased 2,3-diphosphoglycerate concentrations.

Skeletal muscle represents the principal site of lactate turnover. During moderate exercise, blood lactate levels normally remain unchanged despite elevated production. In a progressive (ramp) test, when work rates increase above what is referred to as the “anaerobic threshold,” lactate concentrations increase because the rate of rise in lactate production exceeds its rate of disposal. Although it was formerly thought at this level of exercise that oxygen consumption exceeds oxygen delivery to the muscle cell mitochondria, this now seems somewhat less likely, and increasing lactate concentrations may be linked to rising catecholamine-stimulated nonhypoxic glycolysis.⁴⁰ During vigorous exercise, lactate levels may transiently increase to 20 mEq/L or greater. Excessive production of lactate by skeletal muscles can also be observed during grand mal seizures and may accompany severe shivering in the hypothermic patient (Table 7-3).

Cohen and Woods⁴² divided the causes of lactic acidosis into two types: type A, in which tissue hypoxia is evident, and type B, in which the tissue P_{O_2} appears to be normal. Type A disorders include all forms of shock, acute respiratory distress syndrome, acute hypoxemia, and a variety of conditions that impair oxygen delivery, such as carbon monoxide poisoning and severe anemia. As explained earlier, the actual role of tissue hypoxia in type A disorders remains somewhat controversial. Type B disorders, which are not usually associated with tissue hypoxia, include common illnesses that may be associated with lactic acid accumulation, a variety of drugs and poisons that can induce lactic acidosis (associated with myoglobinemia following propofol administration⁴³), and congenital metabolic enzyme deficiencies. In diabetic patients, low insulin levels reduce the metabolism of pyruvate by pyruvate dehydrogenase, resulting in an increased lactate concentration. Evidence has also been reported that accumulation of ketones in the plasma may inhibit the monocarboxylic acid pump that is responsible for hepatic uptake of lactate.⁴⁴ In some patients with *diabetic ketoacidosis* (DKA), elevated lactate may be caused by extracellular fluid volume depletion due to osmotic diuresis induced by hyperglycemia. Malignancies, particularly lymphoproliferative and myeloproliferative disorders, may result in overproduction of lactic acid. This phenomenon recognized by Otto Warburg and so named appears to represent the need of rapidly growing cells for large amounts of two to three carbon intermediates (such as lactate) necessary to sustain the anabolic requirements of nucleic acid, lipid, and protein metabolism.

Renal or hepatic failure may also lead to lactic acidosis. As noted in Table 7-3, many drugs have been implicated in lactic acidosis, and the presence of polyethylene glycol as an excipient in a wide variety of drug preparations may also be associated with lactic acidosis.

Table 7-3 Causes of Anion Gap Acidosis

LACTIC ACIDOSIS

Type A: Tissue Hypoxia

Poor tissue perfusion: shock due to hypovolemia, sepsis, cardiogenic, idiopathic
Severe hypoxemia: pulmonary disorders (e.g., asthma, excessive inhaled β_2 -adrenergic agents), acute respiratory distress syndrome, carbon monoxide poisoning
Exercise above anaerobic threshold, seizures, shivering
Rhabdomyolysis
Severe anemia, carbon monoxide

Type B: Altered Lactate Metabolism without Hypoxia

Liver disease, renal failure, diabetes mellitus, malignancies (especially hematopoietic), SIRS, HIV
Drugs: acetaminophen, β -agonists, biguanides, cocaine, cyanide, ethanol, diethyl ether, fluorouracil, halothane, iron, methanol, salicylates, ethylene and propylene glycol, isoniazid toxicity, linezolid, nalidixic acid, niacin, zidovudine (AZT), metformin, chemotherapy, nitroprusside and cyanide, propofol, total parenteral nutrition, valproic acid
Rhabdomyolysis
Hereditary: glucose-6-phosphatase deficiency, fructose-1,6-phosphatase deficiency
D-Lactic acidosis

KETOACIDOSIS

Diabetes mellitus
Starvation
Ethanol
Inheritable errors of metabolism

UREMIA

TOXIC ANIONS

Ethylene glycol (glyceraldehyde, oxalate, hippurate)
Methanol (formaldehyde, formate)
Paraldehyde (acetoacetate)
Salicylates
Aminocaproic acid

HIV, human immunodeficiency virus; SIRS, systemic inflammatory response syndrome.

Although L-lactate is usually the cause of lactic acidosis, D-lactate accumulation due to intestinal bacterial metabolism has been documented in patients with short bowel syndrome, bowel ischemia, or obstruction; it can be detected only if an appropriate bacterial enzyme is used in the lactic acid assay.⁴⁴ D-Lactic acidosis can also be expected with use of those Ringer lactate solutions that contain a racemic mixture of lactic acid stereoisomers. However, much of the D-lactate is lost in the urine because, unlike L-lactate, it is not reabsorbed by the renal tubules, and some of the D-lactate is metabolized in mammals.⁴⁵ The anion gap therefore may be relatively normal. D-Lactic acidosis can be associated with neurologic and psychiatric symptoms. It may be treated by avoiding foods that contain lactobacillus (e.g., yogurt and sauerkraut), by decreasing dietary carbohydrates, and by administration of oral antibiotics.

Diabetic Ketoacidosis

Accumulation of acetoacetate, β -hydroxybutyrate, and acetone (“ketone bodies”) in the body is referred to as “ketoacidosis.” This disorder appears to require both

Figure 7-5 Factors encouraging ketoacidosis. Some reactions are stimulated by insulin deficiency (arrow up), whereas others (arrow down) are inhibited by insulin deficiency and increased glucagon. The open curved arrow indicates that acylcarnitine transferase (ACT) I is normally inhibited by malonyl coenzyme A (CoA). FFA, free fatty acid; NAD⁺, nicotinamide adenine dinucleotide (oxidized); NADH, nicotinamide adenine dinucleotide (reduced); VLDL, very-low-density lipoprotein.

increased mobilization of free fatty acids from lipid stores and their excessive conversion within hepatocytes to ketone bodies (Fig. 7-5). Triglycerides within fat are normally broken down by lipase into free fatty acids and glycerol. The activity of lipase is enhanced by low concentrations of insulin and increased concentrations of glucagon, catecholamines, and growth hormone. Free fatty acids released from adipocytes are taken up by the liver and linked to CoA to form acyl CoA. Acyl CoA is either transformed by esterification to triglycerides and lipoproteins or transferred into the mitochondria as a complex with carnitine and then metabolized to carbon dioxide and water in the Krebs cycle or converted to ketone bodies. The fraction of acyl CoA that is transferred into the mitochondrial matrix is increased by raised glucagon concentrations. This transport is mediated by the enzyme acylcarnitine transferase I, which in turn is inhibited by the amount of malonyl CoA present. Normal inhibition of acylcarnitine transferase I by malonyl CoA is indicated by the curved arrow in Figure 7-5. The concentration of malonyl CoA falls when glucagon is increased or insulin deficiency is present, and transport of the acyl fragment into the mitochondrial matrix is consequently increased. Increased glucagon also increases the amount of carnitine present, further accelerating movement of acyl CoA into the mitochondria. The acyl CoA complex entering the mitochondria is degraded successively to form acetyl CoA, which under normal circumstances is incorporated into the Krebs cycle and oxidatively metabolized to carbon dioxide. In DKA the quantities of acetyl CoA produced exceed the capacity of handling by the Krebs cycle and are converted to ketone bodies. Ketoacids are normally taken up and metabolized to carbon dioxide and water by muscle and kidney rather than by the liver, but this process may be reduced in DKA.⁴⁵

An equilibrium normally exists between β-hydroxybutyrate, acetoacetate, and acetone. There is usually two to three times as much β-hydroxybutyrate as acetoacetate, but this ratio may be significantly increased if tissue Po₂ is reduced. Because standard tests for ketones measure acetone (which is not an acid) and acetoacetate but do not detect β-hydroxybutyrate (which is not a ketone), hypoxia may lead to an underestimate of the severity of “ketoacidosis.” In normal subjects the ratio of β-hydroxybutyrate to acetoacetate is 2:1. With DKA this ratio increases to 2.5:1 to 3:1, and with poor tissue perfusion and associated lactic acidosis, it can exceed 8:1.⁴⁶ As insulin sensitivity and volume status improve with therapy, conversion of β-hydroxybutyrate to acetoacetate may increase the amount of ketone bodies detected, which may be misinterpreted as worsening of the ketoacidosis.⁴⁶ Treatment of diabetic ketoacidosis is discussed in detail elsewhere.⁴⁷

Starvation often leads to ketoacidosis within 1 or 2 days, particularly after exercise,⁴⁸ but HCO₃⁻ levels seldom decline below 18 mEq/L. Starvation ketoacidosis is also attributed to decreased insulin concentrations, but these do not fall to levels as low as those encountered in DKA, and there is evidence that ketosis stimulates insulin secretion in those with normal pancreatic function. Alcoholics who binge and then abruptly stop drinking and eating may develop severe ketoacidosis,^{49,50} which may be underestimated because of a disproportionate rise in β-hydroxybutyrate. They usually become dehydrated from vomiting before hospital admission, and they may develop severe acidosis, frequently with concomitant lactic acidosis. Glucose concentrations are frequently low, and glucose (given with thiamine to avoid the Wernicke-Korsakoff syndrome of cerebral beriberi) stimulates insulin secretion and corrects the ketoacidosis. Insulin

must generally be avoided in these patients. Supplementation with K^+ , phosphate, and Mg^{2+} is frequently required. Several congenital errors of metabolism that result in ketoacidosis have also been described. Ingestion of a high-fat diet, paraldehyde, or isopropyl alcohol may also result in a positive test for ketones.

Uremic Acidosis

Renal insufficiency does not usually produce an anion gap acidosis until the glomerular filtration rate falls below 20 mL/min and blood urea nitrogen and creatinine levels increase to more than 40 mg/dL (14.3 mmol/L) and 4 mg/dL (354 μ mol/L), respectively. However, there is some variation in the filtration threshold at which anion gap acidosis develops because of differences in diet and sites of renal damage.⁴⁶ The loss of nephrons is accompanied by a decrease in the ability to excrete both NH_4^+ and anions. Numerous anions normally kept low by normal renal clearance contribute to the anion gap, including sulfate, phosphate, and lactate. With acute renal failure, HCO_3^- concentrations characteristically decline by 1 to 2 mEq/day but decline more rapidly in the presence of hypercatabolism. Hemodialysis becomes necessary when HCO_3^- level falls to less than 10 mEq/L. Milder forms of renal insufficiency may be accompanied by hyperchloremic acidosis (see later discussion).

Toxic Forms of Anion Gap Acidosis

As noted in Table 7-3, numerous substances can be converted to hydrogen ions and anions by metabolism, resulting in an anion gap acidosis. *Central nervous system* (CNS) stimulation by large ingestions of aspirin initially can cause hyperventilation in adults, but this is soon followed by an anion gap metabolic acidosis. Salicylates are themselves anions, but most of the acidosis observed after an overdose is related to formation of organic acids, particularly lactic acid and ketones.⁵¹ With very high aspirin concentrations, red cell HCO_3^-/Cl^- exchange is impaired, and this may lead to tissue carbon dioxide retention, which may not be apparent in arterial blood owing to the previously mentioned ventilatory stimulation. The initial respiratory alkalosis contributes to lactate production. $NaHCO_3$ administration promotes both redistribution of salicylates from tissues to blood and urinary excretion by ionic trapping, but severe alkalosis and K^+ losses must be avoided; hemodialysis may be helpful. Glucose infusions are used to increase the cerebrospinal fluid concentration of glucose, which is frequently decreased.⁵²

Volatile alcohol ingestions are frequent causes of metabolic acidosis, most commonly methanol, isopropanol, or ethylene glycol. Methanol (rubbing alcohol) is converted to formic acid, and ethylene glycol (radiator fluid) is converted to oxalic acid and other toxic anions. Both of these alcohols are metabolized by alcohol dehydrogenase and cause acidosis directly through their metabolites. Although isopropyl alcohol ingestion leads to CNS depression and the presence of urinary ketones (acetone), it is not metabolized to an organic acid, and acidosis is seen only with vascular collapse and lactic acidemia. Ethanol (to a serum concentration of 100 to 150 mg/L), or preferably fomepizole,⁵³ should be used to inhibit the formation of toxic metabolites from

methanol and ethylene glycol, and hemodialysis may be used to clear these metabolites. Toluene, which induces euphoria when inhaled, is converted to benzoic hippuric acids and may cause severe hypokalemia.

Alcohols and ethylene glycol should be suspected if the serum osmolality by freezing point depression exceeds by more than 20 mmol/L the osmolality calculated from laboratory values of Na^+ , glucose, and urea by the following equation:

$$\text{Serum osmolality} = 2 \times [Na^+] + BUN/2.8 + \text{glucose}/18 \quad [9]$$

where sodium is in milliequivalents per liter and *blood urea nitrogen* (BUN) and glucose are in milligrams per deciliter. (Vapor pressure measurements of osmolality should not be used because they do not detect the presence of volatile alcohols.) The “osmolar gap” may also be increased in “pseudohyponatremia” (due to the presence of excess lipid or protein in the plasma) and after administration of mannitol or radiopaque dyes, and these factors also need to be assessed. The mnemonic “mudpiles” is frequently used by clinicians to remember many of the causes for anion gap acidosis (methanol, uremia, diabetic ketoacidosis, propylene glycol, infection, lactic acidosis, ethylene glycol, salicylates).

HYPERCHLOREMIC ACIDOSIS

Metabolic acidosis in the absence of an elevated anion gap is usually associated with hyperchloremia. Hyperchloremic acidosis may be observed in a variety of renal and gastrointestinal disorders, the latter being more common.

Renal Tubular Acidosis

Metabolic acidosis arises from a variety of renal tubular disorders. Disorders of renal tubular function that result in hyperchloremic acidosis can be divided into four categories that can be differentiated by their clinical and laboratory characteristics.⁵⁴⁻⁵⁶ Particular defects in various membrane transport proteins that account precisely for certain inherited forms of *renal tubular acidosis* (RTA) have been identified, but the classic definitions still remain the most useful clinically, and these are outlined here.

Type 1 Renal Tubular Acidosis. Type 1, or “classic,” RTA involves defects in distal tubular acid secretion. Only distal nephrons can produce an acidic urine, so that with injury or dysfunction it is impossible for urine pH to be lowered below 5.3, regardless of how acidotic the patient is. Serum HCO_3^- can be below 10 mEq/L. Urinary HCO_3^- excretion is usually low, because most HCO_3^- is reabsorbed proximally. HCO_3^- infusion therefore can be used to prove that the defect is distal (type 1 RTA) rather than proximal (type 2 RTA): the fraction of filtered HCO_3^- lost in urine remains low in type 1 but is high in type 2 RTA. Another defect observed with type 1 RTA is an inability to generate high PCO_2 in the urine after infusion of HCO_3^- . Normal subjects produce urine with PCO_2 values that exceed those in the plasma by more than 30 to 100 mm Hg. This phenomenon is related to distal tubular H^+ transport to form H_2CO_3 . The subsequent generation of carbon dioxide from HCO_3^- in the distal nephron is relatively slow because there is little carbonic

anhydrase on the luminal surface. Dissipation of the carbon dioxide from urine beyond the collecting ducts is inefficient because of the small surface-to-volume ratio of the lower urinary tract. Because patients are unable to secrete H^+ ions in the distal tubules, their urinary PCO_2 remains less than 40 mm Hg.

As indicated in Table 7-4, many disorders are associated with distal RTA. It can be caused by a wide variety of mutations, most of which affect carbonic anhydrase II, anion exchanger, or the proton pump (H^+ -ATPase) in intercalated cells of the renal cortical collecting duct. Chronic acidosis

leads to osteopenia with Ca^{2+} , Mg^{2+} , and PO_4^{2-} loss in the urine. Precipitation of Ca^{2+} and PO_4^{2-} is normally inhibited by tubular secretion of citrate. As citrate secretion tends to be reduced, this and an alkaline urine with calciuria and hypocitraturia appears to be responsible for nephrolithiasis and nephrocalcinosis that characterize distal but not proximal RTA. K^+ losses tend to be increased because of increased exchange of K^+ for Na^+ in the distal tubule. Concentration defects are common.

In the absence of therapy, acidosis progresses relentlessly in distal RTA because fixed acids cannot be excreted at their rate of production. Hypokalemia may be particularly severe with consequent muscle weakness or even paralysis. Treatment with 1 mEq/kg $NaHCO_3$ daily (roughly the rate of bodily fixed acid generation) is usually sufficient in adults; more is required in children. Bone demineralization is reduced by this therapy, and K^+ losses are minimized.

Type 2 Renal Tubular Acidosis. In type 2 or proximal RTA, HCO_3^- reabsorption is impaired because of a defect in the proximal ion exchange of H^+ for Na^+ , which is mediated by an apical membrane Na^+-H^+ antiporter. Normally, HCO_3^- is completely removed from glomerular filtrate until serum HCO_3^- concentrations exceed 22 to 24 mEq/L, and maximal reabsorption rates are not observed until concentrations are approximately 28 mEq/L. In proximal RTA, maximal reabsorption values may top out at a serum concentration of approximately 18 mEq/L. The distal tubules cannot absorb more than 15% to 20% of the filtered load of HCO_3^- , so HCO_3^- is lost in the urine, causing the urine pH to rise even when the patient is acidotic. When serum HCO_3^- is normalized to 25 mmol/L by HCO_3^- infusion, more than 10% of the filtered HCO_3^- is lost in the urine in type 2 RTA, compared with less than 5% in normal subjects and those with type 1 RTA. If the serum HCO_3^- level falls below the HCO_3^- recovery threshold, then urinary HCO_3^- loss ceases, urine pH falls, and the acidosis does not progress. A typical patient will have a stable serum HCO_3^- value in the range of 12 to 20 mEq/L. It is common to find that patients with proximal RTA do maximally acidify their urine, but only in the presence of a significant metabolic acidosis. In some patients it may be necessary to decrease serum HCO_3^- to less than their usual level with NH_4Cl administration before maximal urine acidification is observed.

Proximal RTA may be an isolated tubular lesion, but it is more frequently associated with other proximal tubular defects that lead to loss of glucose, phosphate, amino acids, and low-molecular-weight proteins (Fanconi syndrome). Nephrolithiasis and nephrocalcinosis are not characteristic, but patients are susceptible to osteomalacia and rickets, if the acidification defect is associated with calcium and phosphate loss. They require much more $NaHCO_3$ (10 to 15 mEq/kg/day) to correct their acidosis than do patients with distal RTA. Sodium citrate is better tolerated than $NaHCO_3$, and thiazides can decrease administered alkali needs. Large amounts of $NaHCO_3$ exacerbate losses of K^+ , and supplements and/or potassium-sparing diuretics are commonly required. Serum phosphate level may be reduced if there is a defect in reabsorption, and alkaline phosphatase level may be increased. Some illnesses associated with proximal RTA are indicated in Table 7-4.

Table 7-4 Causes of Hyperchloremic Acidosis

RENAL TUBULAR ACIDOSIS

Type 1 (Distal, Classic), Hypokalemic

Congenital defects without systemic disease (anion exchanger, AE1 deficient) or with systemic disease (e.g., Ehlers-Danlos syndrome, sickle cell anemia)
 Hyperglobulinemia (e.g., systemic lupus erythematosus, idiopathic pulmonary fibrosis, Sjögren syndrome, thyroiditis, chronic active hepatitis, biliary cirrhosis, vasculitis)
 Drug toxicity (e.g., amphotericin B, toluene, analgesics, lithium)
 Nephrocalcinosis (e.g., primary hyperparathyroidism, vitamin D intoxication, hyperoxaluria, Fabry disease, Wilson disease)
 Tubular and interstitial renal disease (e.g., pyelonephritis and obstructive renal disease, renal transplant rejection)

Type 2 (Proximal), Hypokalemic

Congenital disorders: isolated or associated with mental retardation, ocular abnormalities
 Selective (acetazolamide, sulfonamides) or associated with loss of glucose, phosphate, amino acids, low-molecular-weight proteins, lysozyme, light chains, uric acid
 Genetic (e.g., cystinosis, Wilson disease)
 Dysproteinemias (e.g., multiple myeloma, monoclonal gammopathy)
 Drug or chemical toxicity (e.g., outdated tetracycline, heavy metals, ifosfamide)
 Secondary hyperparathyroidism with hypocalcemia (e.g., vitamin D deficiency or resistance)
 Renal interstitial disease (e.g., medullary cystic disease, Sjögren syndrome, renal transplant)

Type 3

Type 1 and 2 RTA, carbonic anhydrase II deficiency

Type 4, Hyperkalemic

Mineralocorticoid deficiency: Addison disease, tuberculosis, metastatic carcinoma, autoimmune, adrenal hemorrhage, acquired immunodeficiency syndrome (AIDS), critically ill patients, drugs (ketoconazole, phenytoin, rifampin)
 Hyporeninemic states: diabetes mellitus, nephritis, lupus, AIDS
 Mineralocorticoid resistance: pseudohypoaldosteronism (congenital, spironolactone)
 Medications: potassium-sparing diuretics (amiloride, triamterene), angiotensin-converting enzyme inhibitors, trimethoprim, pentamidine, nonsteroidal anti-inflammatory drugs, cyclosporine A, β -adrenergic inhibitors, α -adrenergic agonists, heparin, digitalis overdose, lithium, insulin antagonists (diazoxide, somatostatin), succinylcholine

NONRENAL HYPERCHLOREMIC ACIDOSIS

Diarrhea
 Pancreatic drainage
 Ureterosigmoidostomy
 Cholestyramine (diarrhea), NH_4Cl and hyperalimentation with amino acid infusions, $CaCl_2$
 Toluene exposure (hippurate production)
 Loss of ketones that could have been converted to bicarbonate

Type 3 Renal Tubular Acidosis. A true type 3 RTA includes features of both proximal and distal forms, but it does not have great clinical significance. The largest patient group in this category, rarely seen nowadays, was infants or young children with hereditary distal RTA that manifested some proximal bicarbonate loss transiently. A similar combination of defects is also observed in a small number of patients with an inherited form of carbonic anhydrase II deficiency.

Type 4 Renal Tubular Acidosis. Type 4 RTA is caused by either decreased aldosterone production or tubular hyporesponsiveness to the hormone. Because aldosterone stimulates distal secretion of H^+ and K^+ , deficiency results in hyperchloremic hyperkalemic acidosis, whereas other forms of RTA are usually associated with hypokalemia. Hyperkalemia suppresses proximal NH_3 production. Consequently, even though urine pH may be low, the amount of acid lost may be insufficient to avoid acidosis. A wide variety of disorders lead to low aldosterone production (see Table 7-4), but decreased renin secretion in older patients with diabetic renal disease is common. Aldosterone production decreases in critically ill patients with sepsis and cardiogenic shock. Potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, intravenous solutions, and heparin (which can inhibit aldosterone secretion) may also cause hyperkalemia and type 4 RTA. Hyperkalemia is associated with a high incidence of arrhythmias (25%), hypertension, and weakness.

Most K^+ found in the urine is secreted into the cortical collecting duct, and detection of decreased secretion is facilitated by calculating the *transtubular potassium gradient* (TTKG):

$$TTKG = \{[K^+]_{urine} / [K^+]_{plasma}\} / \{[Osm]_{urine} / [Osm]_{plasma}\} \quad [10]$$

where $[Osm]$ designates osmolality. This ratio corrects the urine-to-plasma potassium ratio for urine concentration, which occurs more distally in the nephron. The TTKG should be greater than 8 in patients with hyperkalemia and should increase after administration of mineralocorticoids in patients with aldosterone deficiency. Failure of TTKG to increase after mineralocorticoids suggests loss of tubular sensitivity.

Acidosis of Progressive Renal Failure. Hyperchloremic RTA without hyperkalemia is characteristic of many renal diseases associated with loss of renal tissue and a decrease in the glomerular filtration rate. Retention of acid in these patients is attributable to a decrease in the ability of the kidneys to excrete NH_4^+ . Although the decline in serum bicarbonate is relatively modest, it is generally recommended that serum HCO_3^- concentrations should be maintained above 22 mEq/L with modest $NaHCO_3$ supplementation to minimize bone reabsorption, insulin resistance, and protein catabolism.⁵⁷

Gastrointestinal Causes of Hyperchloremic Acidosis

Diarrhea is a more common cause of hyperchloremic acidosis than are renal tubular disorders. In the normal bowel, Cl^- is selectively absorbed in exchange for HCO_3^- , more so in the colon than proximally. Normally, stool fluid volume and

Cl^- losses are modest, but, when there is diarrhea, significant amounts of HCO_3^- can be lost. Lactic acid and other organic acids are also produced by bowel microorganisms, and these reduce the actual HCO_3^- stool concentrations.⁵⁸ However, these organic anions are not readily absorbed from the colon with fast transit, and the net result is that HCO_3^- is lost from the body, whereas serum Cl^- is increased without a rise in the anion gap. Absorption of NH_4^+ generated by gut bacteria contributes to the acidosis. Passage of urine into the bowel after ureterosigmoidostomy or ureteroileostomy can also produce hyperchloremic acidosis, because the Cl^- tends to be absorbed instead of the HCO_3^- .

Each liter of diarrheal fluid can result in the loss of 200 mEq of HCO_3^- . Pancreatic and biliary fluids contain 50 to 100 mEq of HCO_3^- per liter, and severe hyperchloremic acidosis can arise after losses of these fluids. Cholestyramine contains an anion-exchange resin that can generate hyperchloremic acidosis by releasing Cl^- in exchange for HCO_3^- . K^+ losses in diarrheal stool (30 to 60 mEq K^+ per liter) in exchange for Na^+ can be severe. Furthermore, extracellular volume depletion promotes aldosterone secretion, which in turn enhances urinary K^+ loss. Chronic acidosis increases renal NH_4^+ secretion, distinguishing it from RTA, which can be detected by measuring the urine net charge (see later).

Miscellaneous Causes of Hyperchloremic Acidosis

Respiratory alkalosis is normally compensated by a decrease in proximal HCO_3^- reabsorption. Correction of respiratory alkalosis may transiently produce a hyperchloremic acidosis, as can some hyperalimentation fluids, NH_4Cl , or $CaCl_2$. Toluene, inhaled by glue sniffers, is converted to benzoic acid and hippurate, which are rapidly renally excreted with cations, resulting in hyperchloremic acidosis. Some intravenous solutions of synthetic amino acids that may be titrated with excess HCl (hydrochloric acid) and saline infusions lower HCO_3^- and increase Cl^- concentrations (see later discussion).

Urine Net Charge and Osmolar Gap

Measurement of the *urine net charge* (UNC), or urine anion gap, can be used to help distinguish between hyperchloremic acidosis due to diarrhea or to RTA. Unlike serum, the urine seldom contains significant HCO_3^- in acidotic patients, but K^+ and NH_4^+ concentrations can be considerable. The UNC is calculated from the following equation:

$$UNC = Na^+ + K^+ - Cl^- \quad [11]$$

If urinary NH_4^+ is high, then urinary Cl^- concentration will exceed that of Na^+ plus K^+ , and the UNC will be negative by 20 to 50 mEq/L. UNC provides an estimate of urine NH_4^+ and is negative with hyperchloremic acidosis caused by diarrhea because renal NH_4^+ production is increased in response to the metabolic acidosis. In contrast, UNC is more positive in patients with RTA, with impaired production and/or excretion of NH_4^+ . The presence of ketones and other anions can also cause UNC to be negative, and direct NH_4^+ measurements provide a more reliable index of renal tubular acid metabolism. NH_4^+ concentrations have also been estimated by calculating the urine osmolar gap, which represents the difference between observed and calculated urine osmolality.

DILUTIONAL ACIDOSIS

A modest acidemia is observed when water dilutes blood after being pulled from cells by increased extracellular solute concentrations such as glucose.⁵⁹ It is generally attributed to the fact that plasma HCO_3^- falls to a greater degree than does PCO_2 , which is regulated by the brain.⁶⁰ Saline infusions may have a similar effect; however, the dilution associated with inappropriate antidiuretic hormone secretion is not usually accompanied by acidosis.⁵⁷

CLINICAL MANIFESTATIONS

Perhaps the most obvious sign of metabolic acidosis is the respiratory response, which consists of slow but deep breathing known as Kussmaul respiration. It is particularly effective because the dead-space contribution to ventilation is minimized. Patients with metabolic acidosis are often asymptomatic, and their hyperventilation may not be clinically obvious. With more severe acidosis, dyspnea may be troubling, and patients complain of headache, nausea, and vomiting. This may be followed by confusion, stupor, and even coma, which are particularly likely to be present in respiratory acidosis. Acidosis may reduce the myocardial catecholamine responsiveness and induce arteriolar vasodilation, but these effects are largely blunted by increased catecholamine and cortisol secretion.⁶¹ Venoconstriction is characteristic of acidosis⁶² and may shift blood into the central volume and trigger pulmonary edema.⁶³ Arrhythmias, including ventricular fibrillation, can be fatal.

Hyperkalemia (despite total body K^+ depletion) is sometimes observed with metabolic acidosis. It is often associated with DKA, but this is related in large part to the plasma hyperosmolality that causes water and K^+ , the main intracellular cation, to exit cells. Infusions of organic acids are much less likely to cause hyperkalemia than are infusions of inorganic acids,⁶⁴ and the conventional wisdom that serum K^+ increases in a predictable fashion with metabolic acidosis⁶⁵ has not proved to be very useful. Nor is hyperkalemia found in most patients with types 1, 2, or 3 RTA or with diarrhea because of the simultaneous losses of both HCO_3^- and K^+ with these disorders.

Chronic retention of more than 10 mEq H^+ per day may be tolerated over a period of years in patients with chronic renal disease because of buffering by bone alkaline constituents (calcium, phosphate, and carbonate).^{66,67} When acid production exceeds the release of bone buffers, a fall in HCO_3^- is inevitable. Recent evidence suggests that the acid load of the typical protein-rich Western diet may not be fully excreted by the kidneys and the very slight failure to eliminate the entirety must be handled by bone buffering. Over many decades of life, this cumulative bone buffering may help to explain the high incidence of osteopenia and osteoporosis in older adults.

THERAPY

Treatment of metabolic acidosis should focus primarily on correcting the metabolic disorder responsible for its emergence and the hemodynamic, oxygenation, and electrolyte derangements that ensue, rather than the acidemia itself. For example, insulin and volume replacement are the

mainstays of diabetic therapy, dialysis for uremic acidosis, and reversal of shock, local ischemia, and hypoxemia for lactic acidosis. If another illness is responsible for lactic acidosis (see Table 7-3), then appropriate therapy must be selected.²

NaHCO_3 administration or other alkaline agents for metabolic acidosis is clearly indicated in patients with chronic metabolic acidosis, such as those with significant hyperchloremic acidosis (e.g., RTA) to prevent bone and muscle catabolism, relieve exertional dyspnea, and promote growth in children. In acute severe metabolic acidosis (especially the endogenous anion gap acidoses), it is becoming clear that HCO_3^- administration is not always helpful or effective. However, alkalinizing agents are still indicated to counter the associated severe hyperkalemia or to enhance excretion of acid metabolites of certain toxins.⁶⁸ In severe DKA despite arterial pH as low as 6.8, bicarbonate administration does not alter rates of glucose correction or ketoacid clearance when compared with equivalent sodium administration given as NaCl. Equivalent evidence in sepsis, severe hypoxemia, and cardiogenic shock (again in randomized saline-controlled studies described previously for DKA) found no obvious benefits and often slightly worse parameters in the bicarbonate-treated patients (for review of these studies, see Swenson⁶⁹). A number of possible negative consequences of attempted alkalization in these conditions have been recognized.^{68,70-73} These include a shift of the oxygen-hemoglobin dissociation curve to the left that may impair oxygen delivery in already hypoxic tissues, greater lactic acid production or suppression of hepatic lactate clearance with an increase in pH, and nonmetabolic generation of carbon dioxide from HCO_3^- with paradoxical intracellular acidosis. Increases in PCO_2 associated with NaHCO_3 may not be observed in the arterial blood even though mixed venous PCO_2 is significantly increased. Excessively rapid infusions of NaHCO_3 may result in a paradoxical diminution of cerebrospinal fluid and brain interstitial pH if they reduce the drive to breathe. Equilibration of HCO_3^- with the cerebrospinal fluid is much slower than the corresponding equilibration of carbon dioxide, and the rise in PCO_2 caused by hypoventilation tends to make the cerebrospinal fluid more acid before the HCO_3^- can diffuse into this compartment. Because the usual alkaline solutions administered are extremely hypertonic, there may be an abrupt fall in serum K^+ as potassium is returned to the cellular compartment. NaHCO_3 infusions should be kept as low as possible (usually <200 mmol) to avoid volume overload, which may alternatively be minimized by hemodialysis against a NaHCO_3 solution. As the underlying disorders improve, both ketone bodies and lactate may be metabolized to HCO_3^- , resulting in the development of posttherapeutic alkalosis. Although it is often claimed that when the pH is much lower than 7.2, NaHCO_3 infusions may prove to be lifesaving by enhancing cardiac contractility and response to pressors, the supporting data are rather unconvincing. As mentioned previously in studies comparing equivalent NaCl and NaHCO_3 , any brief benefits noted with bicarbonate in blood pressure may simply be the result of volume expansion by any sodium-containing fluid. Regardless of the cause of acidemia, if base administration is considered necessary, NaHCO_3 is preferable to lactate solutions, because lactate is completely ionized at any pH still compatible with life and it does not

provide buffering until it is converted to HCO_3^- by normal hepatic function.

As a first estimate of the amount required to raise serum HCO_3^- by a given number of milliequivalents per liter, it is common practice to assume that HCO_3^- enters a space 40% or 50% of the total body weight. Not infrequently, much more is required to repair the deficit. However, no attempt should be made to increase the pH to more than 7.2 with such infusions, and it is prudent to raise the HCO_3^- concentration no more than halfway toward normal during the first day. Determinations of arterial blood PO_2 , PCO_2 , HCO_3^- , pH, glucose, and electrolytes must be repeated at frequent intervals to monitor the response to therapy.

However, given the failure of controlled trials to show any benefit with bicarbonate administration in the most severe endogenous anion gap metabolic acidoses and the negative observations alluded to earlier, it may be better, although difficult, to refrain from using alkalinizing fluids at all in these circumstances. In fact, animal organ and cellular studies reveal the surprising and counterintuitive findings that recovery from ischemia or oxygen deprivation is clearly enhanced when the perfusing media is acidic and recovery is worse under alkalotic conditions, a phenomenon termed “the pH paradox.”⁶⁸ Many explanations have been offered, the most intriguing being that acidosis may blunt the activity of many enzymes and proteins responsible for much of the associated excessively activated oxidative and proinflammatory pathways in hypoxic and septic injuries that may perpetuate ongoing injury. Another potential argument against aggressive attempts to reduce lactic acidosis, independent of treating the initial cause(s), is the failure of dichloroacetate, a compound that stimulates pyruvate dehydrogenase activity and pyruvate entry into the mitochondria, to alter outcomes in patients with severe lactic acidosis.⁷⁴ By limiting lactate formation, the drug may deny cells a preferred fuel under stress.⁴⁰

METABOLIC ALKALOSIS

GENERAL CONSIDERATIONS

For both diagnostic and therapeutic reasons, it is helpful to divide the causes of metabolic alkalosis into those associated with a decrease in the extracellular volume (chloride-sensitive) and those associated with a normal or increased extracellular volume (chloride-resistant)^{74a} (Table 7-5).

CHLORIDE-RESPONSIVE ALKALOSIS

Gastrointestinal Losses

As indicated previously, upper gastrointestinal tract acid losses generate an alkalosis that is initially associated with increased renal Na^+ excretion. *Extracellular fluid* (ECF) volume depletion causes the glomerular filtration rate to fall and is associated with increased aldosterone secretion. This enhances HCO_3^- reabsorption, and alkalosis persists even after all initiating factors (e.g., protracted vomiting and continuous nasogastric suction) have abated. In these patients, Cl^- is avidly reabsorbed from the tubules, and urine concentrations remain lower than 10 mEq/L. Correction of

Table 7-5 Causes of Metabolic Alkalosis

LOSS OF H^+ FROM THE BODY

Chloride-Responsive with Urine $\text{Cl}^- < 20$ mEq/L and Normotension

Gastrointestinal losses of chloride: stomach (vomiting, aspiration, some villous adenomas, congenital chloride-wasting diarrhea, high-volume ileostomy drainage)
Renal losses of chloride: loop and thiazide diuretics, posthypercapnic
Sweat losses of chloride: cystic fibrosis
Posthypercapnia: elevated HCO_3^- after resolution of chronic respiratory acidosis

Chloride-Resistant with Urine $\text{Cl}^- > 20$ mEq/L and Hypertension

Hyperaldosteronism (primary or secondary), Cushing syndrome, cortisol 11- β -ketoreductase deficiency, licorice, etc.
Liddle syndrome: increased epithelial sodium channel (ENaC) in collecting duct

Chloride-Resistant with Urine $\text{Cl}^- > 20$ mEq/L, Hypotension or Normotension

Bartter syndrome: impaired reabsorption of sodium ions and chloride ions in the thick ascending loop of Henle (variants)
Gitelman syndrome: impaired thiazide-sensitive sodium/chloride transporter (NCCT) in the distal convoluted tubule

EXCESSIVE INTAKE OF HCO_3^-

Milk-alkali syndrome
Administration of poorly absorbed anions (e.g., penicillin)
Bicarbonate dialysis in end-stage renal disease
Recovery from ketoacidosis or lactic acidosis after bicarbonate administration
Massive blood transfusions (citrate)

EXTRACELLULAR FLUID VOLUME REDUCTION

the metabolic alkalosis depends on replacement of Cl^- losses, principally given as saline. Although diarrhea usually generates a hyperchloremic acidosis (see earlier discussion), alkalosis may rarely be seen with Cl^- - HCO_3^- exchange across the ileal mucosa⁷⁵ and in a minority of villous adenomas of the colon.

Diuretics

These agents are the most common cause of excessive renal fluid losses. When Na^+ delivery to the distal nephron persists despite extracellular volume depletion (e.g., after diuretic therapy), H^+ secretion by this segment is enhanced. In these conditions, Cl^- concentrations in the urine may be appreciable. Both loop diuretics (furosemide, bumetanide, ethacrynic acid) and thiazides can promote H^+ and K^+ secretion from the more distal segments of the nephron. This frequently results in severe hypokalemic alkalosis.

Sweat

Metabolic alkalosis has also been reported in patients with cystic fibrosis, who tend to lose proportionately more Cl^- than HCO_3^- in their sweat.

Mechanical Ventilation

Alkalosis is not infrequently observed in mechanically ventilated patients treated for chronic hypercapnia. Care must be taken to avoid abrupt increases in ventilation, which may result in life-threatening metabolic alkalosis. The arterial

pH and plasma levels of HCO_3^- of these persons may remain high and inhibit spontaneous ventilation unless Cl^- losses are restored, generally in the form of KCl. Acetazolamide may also be helpful because it inhibits renal tubular HCO_3^- reabsorption, but its use requires careful monitoring in those not mechanically ventilated with limited lung function (forced expiratory volume in 1 second < 1 L) and avoided in those with renal or hepatic insufficiency.

Nonreabsorbable Anions

Sodium salts of penicillin or other anions that cannot be reabsorbed by the renal tubules may stimulate acid and K^+ losses in patients who are volume depleted.

CHLORIDE-RESISTANT ALKALOSIS

Metabolic alkalosis may also be associated with either normal or increased ECF volume, particularly in the presence of excessive aldosterone secretion. Mineralocorticoids act to increase both H^+ and K^+ secretion and Na^+ retention by the distal nephron. This results in a hypokalemic alkalosis that is associated with a modest ECF volume expansion. Na^+ and Cl^- retention appears to be limited by ECF expansion, and output and intake of Na^+ become equal. Unlike situations in which the ECF is decreased, Cl^- is lost in the urine with metabolic alkalosis that is caused by excessive mineralocorticoid secretion (urine $\text{Cl}^- > 20$ mEq/L). Maintenance of the metabolic alkalosis is a result of persistent excess mineralocorticoid secretion as well as hypokalemia.

Any alteration in the renin-angiotensin-aldosterone axis that promotes aldosterone secretion also causes this form of metabolic alkalosis (see Table 7-5) by its stimulatory effects on two different populations of cells in the distal nephron.⁷⁶ Distal tubular exchange of K^+ for Na^+ appears to be confined to principal cells, located in the cortical collecting duct. Because more Cl^- ions than cations are left behind, a negative lumen potential is established that facilitates H^+ secretion by the more distally positioned alpha intercalated cells. Patients with edema due to liver disease, nephrotic syndrome, or congestive heart failure may secrete excessive aldosterone because their effective arterial blood volume is reduced, even though their total ECF volume is increased. The development of hypokalemic alkalosis is particularly likely when they receive diuretics.

The pathogenesis of several forms of congenital hypokalemic, hypochloremic metabolic alkalosis not associated with hyperaldosteronism (Bartter syndrome and Gitelman syndrome) has been traced to abnormalities in renal tubular transporters.⁷⁷

EXCESSIVE INTAKE OF ALKALI

Although the kidneys normally can excrete large quantities of HCO_3^- , metabolic alkalosis may occasionally be generated by excessive intake of HCO_3^- or other anions that are metabolized to HCO_3^- , especially in patients with renal insufficiency. For example, metabolic alkalosis may be observed in patients who ingest extremely large amounts of HCO_3^- and milk (milk-alkali syndrome, which is associated with renal calcification), after fasting (due to conversion of ketones to HCO_3^-),⁷⁴ and after transfusions of large amounts of blood (conversion of citrate to HCO_3^-).⁷⁸ In the absence of volume

depletion or renal disease, alkalosis due to increased HCO_3^- intake rapidly resolves once intake is restricted.

EXTRACELLULAR FLUID CONTRACTION

Water loss from plasma may induce a modest alkalemia that is sometimes referred to as a “contraction” alkalosis and is related to the relatively greater increase of HCO_3^- , compared with PCO_2 . It would probably be more appropriate to designate this as a *concentration alkalosis* to distinguish it from the alkalosis of contraction that is caused by ECF fluid depletion, which promotes renal acid excretion and alkalemia (see earlier discussion).

CLINICAL MANIFESTATIONS

Metabolic alkalosis frequently remains asymptomatic and is often untreated even after discovery. Nevertheless, it may be associated with significant mortality, particularly when $\text{pH} > 7.5$ and $[\text{HCO}_3^-] > 45$ mM.⁷⁹⁻⁸¹ Alkalosis tends to increase the affinity of hemoglobin for oxygen, thereby reducing oxygen delivery to the tissues. It also decreases ventilation by suppressing the carotid body and may constrict the peripheral vasculature, further limiting oxygen supply to tissues.

Neuromuscular hyperirritability may be observed in alkalosis and has been attributed in part to increased calcium binding to albumin. Twitching and tetany may be preceded by the Chvostek and Trousseau signs, and seizures can ensue. Metabolic alkalosis is usually associated with hypokalemia, which may be responsible for both supraventricular and ventricular arrhythmias.⁸⁰ Alkalosis promotes intracellular movement of K^+ and may also cause an increase in the anion gap because of removal of H^+ from albumin and increased generation of lactate.

THERAPY

Treatment of metabolic alkalosis depends on the status of the ECF volume. Patients with ECF volume loss can be distinguished from those with excess volume on the basis of urine Cl^- , which is usually less than 10 mEq/L in the former and greater than 20 mEq/L in the latter setting. For patients who have sustained severe volume losses, fluids that contain Na^+ , Cl^- , K^+ , and Mg^{2+} are frequently indicated.

Fluid administration to edematous patients with alkalosis is usually inappropriate. Spironolactone is useful in the presence of excessive mineralocorticoid secretion. The carbonic anhydrase inhibitor acetazolamide may be helpful in patients with posthypercapnic alkalosis, although it may increase loss of K^+ and occasionally cause liver damage and hepatic encephalopathy. Although NH_4Cl and arginine hydrochloride may be used to treat alkalosis, their use must be avoided in patients with severe liver disease because these agents may precipitate hepatic coma by decreasing urea synthesis and/or elevating NH_3 concentrations. They may also induce hyperkalemia and increase urea levels in patients with azotemia.

Infusions of HCl (at a concentration of 100 to 200 mEq/L) may be safer than NH_4Cl in patients with liver and kidney disease, but these infusions require central access confirmed

radiologically by location of the catheter tip in the superior vena cava to minimize the likelihood of tissue necrosis and hemolysis caused by the acid infusion. Alternatively, intubation and intentional hypoventilation to increase the PCO_2 , thereby reducing arterial pH, may be employed. Severe metabolic alkalosis can also be treated by hemodialysis. Histamine H_2 receptor antagonists or gastric proton pump ($\text{H}^+/\text{K}^+\text{-ATPase}$) inhibitors are useful in patients receiving nasogastric suction.

RESPIRATORY ACIDOSIS

GENERAL CONSIDERATIONS

Respiratory acidosis is a frequently frustrating problem for patients with respiratory insufficiency. PCO_2 is normally kept within narrow limits by the respiratory center within the CNS. Chemoreceptors that respond to changes in PCO_2 are present in the medulla, close to the floor of the fourth ventricle, and in the carotid bodies. Both sites are stimulated by pH changes associated with alterations in PCO_2 . Normally, arterial PCO_2 is controlled primarily by the central chemoreceptors, which may have increased sensitivity because of concomitant hypercapnic peripheral chemoreceptor input. However, they may be suppressed by chronic hypoxia and hypercapnia, mostly in patients with severe COPD. When this happens, ventilation is maintained by the carotid bodies responding to alterations in PO_2 and pH. If PO_2 is raised excessively, carotid body output may be suppressed, leading to progressive hypercapnia and narcosis. Acute increases in PCO_2 are buffered by non- HCO_3^- buffers to form HCO_3^- , but HCO_3^- concentrations seldom exceed 30 mEq/L during the first 24 hours of hypercapnia. Increases in PCO_2 result in an intracellular acidosis within the renal tubular cells that favors acid excretion, and over the next few days, acid excretion is accelerated by a rise in NH_4^+ formation.

CAUSES

Any process interfering with ventilation can lead to respiratory acidosis (Table 7-6; see also Chapter 99). COPD is the most frequent cause of this problem, related primarily to mechanical conditions that decrease alveolar ventilation. Interstitial lung disease is less likely to increase PCO_2 values unless it becomes severe. Extensive infiltrative processes (including pneumonias and all forms of pulmonary edema) and large pleural effusions can decrease alveolar ventilation. With significant acute pulmonary artery embolic obstruction, wasted ventilation due to increased alveolar dead space can explain sudden increases in ventilation, or hypercapnia may ensue if ventilation cannot be increased. In such situations, dead-space ventilation may be measured directly by sampling both arterial blood and mixed expired gases. A paralyzed diaphragm or extensive rib fractures that lead to a unilateral flail chest can produce an inefficient mode of ventilation.

Hypoventilation is the most serious complication of a wide variety of neuromuscular disorders (see Table 7-6). The central respiratory centers may be depressed acutely or chronically by narcotics or by any process that injures the

ABNORMALITIES IN BLOOD CO_2 TRANSPORT

Decreased perfusion: heart failure, cardiac arrest with cardiopulmonary resuscitation, extensive pulmonary embolism, severe anemia
Carbonic anhydrase inhibition—high-dose acetazolamide

brain stem, including chronic hypoxemia and hypercapnia. A complex disturbance of the respiratory center may be encountered in patients with the obesity-hypoventilation syndrome. Apneic episodes during sleep are common in these persons and are related to airway obstruction or to a central failure to initiate ventilation, or both.

Rarely, if cardiac output is low, if anemia is severe, and/or if certain drugs are used that interfere with the normal high efficiency of red cell carbon dioxide transport and exchange (see Table 7-6), carbon dioxide retention in the tissues may develop and yet not be reflected in the arterial PCO_2 .^{82,83} In fact, as carbon dioxide rises in the vicinity of the central chemoreceptors, ventilation may be stimulated sufficiently to cause a paradoxical arterial hypocapnia that can be mistaken as evidence of a primary respiratory alkalosis. If PCO_2 is measured in the venous circulation (mixed venous PCO_2), one will find an elevated PCO_2 and lower pH, revealing the true state of carbon dioxide homeostasis.

CLINICAL MANIFESTATIONS

If hypoventilation is caused by neuromuscular or mechanical problems, the patient will be dyspneic and tachypneic. In contrast, if the respiratory center is impaired, ventilation may be reduced without any sensation of dyspnea.

The physiologic and clinical consequences of respiratory acidosis tend to be more serious in acute than in chronic states. Elevations in PCO_2 cause systemic vasodilation that is particularly evident in the cerebral circulation. Cerebral blood flow and intracerebral pressures increase and may lead to a picture of pseudotumor cerebri with papilledema, retinal venous distention, and retinal hemorrhages. The

patient may complain of dyspnea and manifest myoclonic jerks, asterixis, tremor, restlessness, and confusion. Coma may be observed at PCO_2 values of 70 to 100 mm Hg when the onset of hypercapnia is abrupt. Significantly higher levels may be well tolerated in patients with chronic respiratory acidosis, who have much higher HCO_3^- concentrations from renal compensation. Peripheral vasodilation and increased cardiac output promote warm, flushed skin and a bounding pulse. Arrhythmias are observed occasionally. Mild increases in serum phosphate and K^+ and decreases in lactate and pyruvate have been described in acute respiratory acidosis, and serum Na^+ may increase modestly in both acute and chronic hypercapnia.

THERAPY

Treatment of respiratory acidosis depends on the restoration of adequate ventilation. In COPD, attention must be focused on bronchodilation, adequate oxygen supplementation, and relief of anxiety or other causes of an increased metabolic rate. Indiscriminate and uncontrolled administration of high concentrations of oxygen should be avoided. The phenomenon of oxygen-induced hypercapnia in these patients is usually observed in the emergency department and intensive care unit when patients present severely hypoxemic, already hypercapnic, and fatigued. Sudden correction of arterial hypoxemia causes further hypercapnia by a combination of three mechanisms: (1) by depression of a high hypoxia-driven peripheral chemoreceptor drive that causes more hypoventilation, (2) by relief of hypoxic pulmonary vasoconstriction in poorly ventilated lung regions that further reduces the ability of the lung to eliminate carbon dioxide as local perfusion to poorly ventilated regions increases, and (3) by saturation of hemoglobin with oxygen that causes previously buffered protons on deoxyhemoglobin to be released with subsequent generation of new carbon dioxide from HCO_3^- stores (Haldane effect). Low-flow oxygen generally suffices to increase PO_2 to satisfactory levels (60 mm Hg and arterial oxygen saturation [arterial SO_2] $\approx 90\%$); greater elevations are neither needed nor advisable. If the use of a ventilator becomes necessary, care must be taken that PCO_2 is not decreased by more than 10 mm Hg each hour to avoid life-threatening metabolic alkalosis. If opiates are responsible for central respiratory depression, the respiratory acidosis may be relieved by naloxone. Aminophylline acts as a respiratory center stimulant, but blood levels must be monitored carefully. Bicarbonate is generally contraindicated because it tends to decrease respiratory drive and increases carbon dioxide levels in the tissues.

“Permissive hypercapnia” with gradual increases in PCO_2 of 10%/hr to levels as high as 100 mm Hg may help mitigate lung damage by barotrauma associated with mechanical ventilation. This approach is frequently used in patients with acute lung injury, acute respiratory distress syndrome, neonatal respiratory failure, or asthma by hypoventilation with tidal volumes less than 7 mL/kg and plateau pressures less than 30 to 35 cm H_2O . The value of bicarbonate infusions to reverse acidosis in these patients remains uncertain. Permissive hypercapnia should be avoided in those with head trauma, increased intracerebral pressure, or cardiac dysfunction.

RESPIRATORY ALKALOSIS

GENERAL CONSIDERATIONS

Although respiratory alkalosis is a common disorder and at times is a serious prognostic sign, it seldom has a significant impact on the clinical status of patients and generally requires little in the way of specific therapy to reverse the hyperventilation directly. Changes in pH related to hyperventilation are quickly moderated by tissue buffering and, to a lesser extent, by release of lactic acid, as described earlier. However, HCO_3^- concentrations do not usually fall below 18 mEq/L acutely, and even with renal compensation, a HCO_3^- concentration below 16 mEq/L should raise the possibility of an independent metabolic acidosis.

CAUSES

It is convenient to divide the causes of respiratory alkalosis into three major categories: hypoxia, pulmonary diseases, and CNS disorders (Table 7-7). Both central (arterial) and peripheral (capillary) hypoxia are causes of hyperventilation. Decreases in arterial PO_2 stimulate the carotid bodies directly. In contrast, tissue hypoxia caused by decreased cardiac output, shock, severe anemia, or excessive hemoglobin oxygen affinity results in the production of lactic acid and other stimuli, which are sensed in blood by the carotid chemoreceptors and by other less well defined chemoreception in the affected tissues themselves. Acute ascent to altitudes greater than 8000 feet may lead to acute mountain sickness. Symptoms generally include dyspnea, malaise, headache, insomnia, anorexia, nausea, vomiting, periodic respiration, and tachycardia. These hypoxic manifestations diminish gradually over a few days with acclimatization.

Many pulmonary disorders are associated with hyperventilation. Hypoxia certainly plays a role but, in addition, receptors have been described in lung tissue that are

activated by local irritant stimuli and fluid accumulation and remain activated even after hypoxemia has been corrected.

CNS disorders are among the most common causes of respiratory alkalosis. Anxiety can provoke hyperventilation (hyperventilation syndrome). Central stimulation of respiration is also common in a wide variety of intracerebral injuries. Many drugs and hormones (notably salicylates, theophylline, and progesterone) stimulate ventilation (see Table 7-7), and hyperventilation may be an early sign of both sepsis due to gram-negative bacteria and hepatic insufficiency due to the accumulation of ammonia and amines that are known to be responsible for respiratory center stimulation.

CLINICAL MANIFESTATIONS

Many manifestations of respiratory alkalosis may be related in part to a fall in free serum Ca^{2+} due to increased binding to serum proteins. Phosphate may also decline slightly and sometimes fall to rather low concentrations in patients who have prolonged severe respiratory alkalosis. It has been suggested that this decline in phosphate is related to activation of glycolysis and phosphorylation of the glucose metabolites thereby produced. Mild hyponatremia and hyperchloremia, as well as hypokalemia,⁷⁰ have also been reported in patients with acute respiratory alkalosis. Some of the CNS changes of acute respiratory alkalosis may be caused by hypocapnic cerebral vasoconstriction leading to reduced blood flow and tissue hypoxia. Often, deliberate hyperventilation is used to reduce cerebral blood flow in states of impending brain herniation from high intracranial pressure, but evidence is mounting that it is useful only for a few hours as a temporizing measure to allow more definitive pressure relief by other means.

Panic, weakness, and a sense of impending doom are common, as are paresthesias and muscle weakness or cramping. As in metabolic alkalosis, Trousseau and Chvostek signs can often be elicited, and overt tetany or seizures may follow, particularly in patients with previous seizure diatheses. Vision and speech may become impaired, and syncope can follow. Transient electrocardiographic changes can resemble those of myocardial ischemia; this finding can be particularly misleading because it is not uncommon for hyperventilating patients to complain of chest discomfort. Indeed, acute hypocapnia, for example with mechanical ventilation, can induce coronary artery spasm, angina, ominous cardiac arrhythmias, and ST elevations in patients with coronary artery disease. Acute respiratory alkalosis can increase serum chloride level and lactate and anion gap concentrations and reduce serum K^+ concentrations.

THERAPY

Reassurance and rebreathing in a small paper bag are frequently all that is needed to control hyperventilation associated with anxiety attacks. In more severe cases, β -adrenergic inhibitors have proved useful, and specific therapy for anxiety may be indicated. Administration of acetazolamide or corticosteroids before ascent to high altitudes may prevent acute mountain sickness in susceptible persons. Ventilation is stimulated by acetazolamide, but the mechanism by which corticosteroids work remains unknown.

Correction of respiratory alkalosis in other conditions, such as hepatic coma and pulmonary disorders, depends on treatment of the primary disorder. Carbon dioxide inhalation by patients with hepatic coma has not been helpful.

Key Points

- Clinical acid-base analyses should be consistent with the Brønsted-Lowry terminology, which has supplanted older definitions that are not sufficiently comprehensive or precise. The use of pH is preferable to hydrogen ion concentration for quantifying acidity.
- Arterial PCO_2 provides a suitable “respiratory” criterion for determining whether alveolar ventilation is appropriate for the rate at which carbon dioxide is produced in the body. Abnormalities in arterial PCO_2 may be “primary” causes of abnormal pH or “secondary” responses, which minimize pH disturbances.
- A “metabolic” disorder refers to a net accumulation or loss of nonvolatile acids and bases from the body and can be primary or secondary. Both the kidneys and other organs, including the gastrointestinal tract and skin, may be involved. No single parameter represents an ideal index of in vivo metabolic acid-base disorders, but the traditional use of HCO_3^- is probably the easiest to use for distinguishing among primary, compensatory, and mixed disorders.
- Incorporation of electrolyte concentrations into the analysis permits calculation of the anion “gap” and strong ion differences and identification of various processes involved in both metabolic acidosis and alkalosis. However, these measurements must always be accompanied by measurement of conventional acid-base parameters (pH_a , arterial PCO_2 , and HCO_3^-).
- Correction of the underlying metabolic or respiratory disorder represents the most effective way to treat the acid-base disorder.

INTRODUCTION

The major function of the lung is to facilitate gas exchange between the air and blood compartments, which takes place in the alveolar region of the lung. In the adult lung, the alveolar-capillary barrier that permits efficient gas exchange is formed by thin cytoplasmic extensions of *alveolar type I* (TI) cells and capillary endothelial cells, separated by a common fused basement membrane.¹

The alveolar surface area comprises more than 99.5% of the large internal surface area of the lung,² estimated in the adult human to be approximately 100 to 150 m². Efficient diffusion of gases between the air and blood is dependent on the thin aqueous/lipid lining layer and the cellular compartments (epithelial, interstitial, and endothelial). Capillaries are located in the interalveolar septum that bridges different alveolar surfaces.³ On the air side, the alveolus is lined by two morphologically distinct epithelial cells, TI and *alveolar type II* (TII) cells. The morphologic and morphometric characteristics of both TI and TII cells are remarkably constant over an approximately 10,000-fold range in mam-

malian lung size,⁴ from which one may infer that there is a conservation of functions of both cell types. Although the distinctive anatomic features of alveolar cells permit the efficient diffusion of gases by forming a thin cellular barrier, alveolar epithelial cells have also evolved to perform other necessary functions, including producing pulmonary surfactant, maintaining an optimal alveolar liquid layer by regulating ion and water transport, protecting against inhaled toxins and infecting agents, and repairing the alveolar epithelium following lung injury or inflammation.^{4,5}

Pulmonary surface-active material (surfactant) is critical for normal lung function. Without surfactant, the work of breathing increases markedly and respiratory distress develops rapidly. In the absence of surfactant the work of breathing may increase from less than 2% to more than 10% of total oxygen consumption. Surfactant provides the low surface tension at the air-liquid interface that is necessary to prevent atelectasis, alveolar flooding, and severe hypoxia. A complex but highly regulated process has evolved for the synthesis, secretion, and reutilization of surface-active material. In addition to its well-recognized

property of providing alveolar stability, surfactant is also important for maintaining the patency of small airways and preventing alveolar flooding.

This chapter reviews the functions of TI cells and TII cells, the physiologic properties of pulmonary surfactant, the use of surfactant replacement therapy in the treatment of hypoxic respiratory failure (*newborn respiratory distress syndrome* [NRDS]), and the role of the alveolar epithelium and surfactant in selected lung diseases. Additional discussion of the alveolar epithelium can be found in Chapter 1, and comprehensive reviews of *acute respiratory distress syndrome* (ARDS) can be found in Chapter 100.

ALVEOLI

The number of alveoli in a lung is largely dependent on the size of the lungs, with larger lungs containing more alveoli. On average, Ochs and colleagues⁶ have estimated that the adult human lung contains approximately 480 million alveoli, each approximately 4.2×10^6 cu μ in size. Recently, the number of the alveoli in the mouse lung has been estimated to be 560 in young mice (12 weeks) and 880 in old mice (91 weeks); these estimates were derived by use of computed tomography imaging, a technique that is quite different from traditional stereology, and may allow quantitative measurements in disease and lung injury models.⁷ In the adult lung, the average alveolar fluid depth is estimated to be 0.14 to 0.20 μ m.⁸

ALVEOLAR EPITHELIAL INTERCELLULAR JUNCTIONS

Early physiologic studies⁹ demonstrated that transport of water and low-molecular-weight solutes out of the pulmonary capillaries is rapid, whereas transport of solutes out of the alveoli is extremely slow. The anatomic basis for the barrier function of the alveolar epithelium became clear from freeze-fracture studies of the lung^{10,11} that demonstrated that epithelial intercellular junctions had morphologic characteristics of “tight junctions,” in contrast to endothelial intercellular junctions that had morphologic characteristics of gap or “leaky” junctions.

Epithelial cells are attached to one another at their lateral membranes by a series of different junctional complexes, including tight junctions, adherens junctions, and gap junctions. These junctional complexes are each composed of different proteins that convey specific functions. Although both tight junctions and adherens junctions associate with the actin cytoskeleton, they have somewhat different functions; tight junctions regulate paracellular movement of ions and solutes, whereas adherens junctions mediate cell-cell adhesion and participate in cell signaling.

The most apical of the intercellular junctions is the tight junction or *zona occludens* (e.g., “closing belt”). By ultrastructural analyses, tight junctions appear as a series of anatomic appositions between the lateral membranes of adjacent cells that extend in a beltlike network surrounding cells, attaching them to adjacent cells and forming a continuous seal. The tight junction is the major factor in

determining paracellular permeability. In addition to the “barrier” functions that regulate the passage of water, ion, and various molecules through paracellular spaces, tight junctions also have a “fence” function, which prevents intermixing of proteins and lipids in the apical and lateral membranes, establishing cell polarity. The tight junction is composed of a dynamic complex of proteins that include transmembrane proteins, cytoplasmic scaffolding proteins, signaling proteins, and adaptors that link to the cytoskeleton. Claudins play key roles in forming tight junction strands and determining paracellular permeability.¹² Permeability can be further modulated by various other factors, including Rho-associated protein kinase, protein kinase C, and other kinases, as well as various cytokines, growth factors, and hormones.¹³

A second type of intercellular junction, the adherens junction, is located more basally. Adherens junctions are composed of clusters of adherens molecules, such as vascular endothelial-cadherin, β -catenin, and plakoglobin, linked to the actin cytoskeleton. There are also associations with kinases, phosphatases, and growth factor receptors. Complex intermolecular interactions mediate cell-cell adhesion and modulate cell signaling from growth factors and from mechanical forces such as sheer stress. Adherens junctions play important roles in both development and wound healing. The complex field of adherences junctions has been well reviewed.¹⁴⁻¹⁶

A third type of junction, the gap junction, is ubiquitous in most mammalian tissues. Gap junctions are composed of connexins, proteins that form intercellular channels, enabling the diffusion of molecules throughout interconnected cells, enabling cells to function in a coordinated measure. In the alveolar epithelium, gap junctions mediate intercellular calcium fluxes, which play a role in surfactant secretion.¹⁷

ALVEOLAR TYPE I CELLS

In the mammalian lung, TI cells comprise only approximately 10% of the cells in the alveolar region but cover more than 95% of the internal alveolar surface area; TII cells (\approx 18% of alveolar cells) cover the remaining less than 5% of the surface area.⁴ TI cells are large (surface area $\approx 7 \times 10^3$ sq μ m) squamous cells with thin cytoplasmic extensions that form the epithelial component of the air-blood barrier. The cytoplasmic extensions of TI cells are only 50 to 100 nm thick, below the resolution of conventional light microscopy. Prior to the development of the electron microscope, there was intense debate about whether the lining of the lung was cellular or acellular. Electron microscopic studies definitively demonstrated that the alveolar surface was lined by a continuous epithelium.^{18,19} TII cells are much smaller cells (\approx 30% of the volume and 3% of the surface area of TI cells) that are often, but not always, cuboidal in shape (Fig. 8-1).⁴ Both TI cells and TII cells are not necessarily confined to one side of the alveolar septum but can bridge two or three different alveoli¹⁹ (see Fig. 8-3B). These complex three-dimensional morphologic relationships may complicate simple interpretations of cellular function that assume distinct apical, basal, and lateral membrane domains.³

Figure 8-1 Immunofluorescent TI and TII cells in the mouse lung. The majority of the alveolar epithelial surface area is composed of TI cells. Transgenic mouse with TII cells expressing enhanced green fluorescent protein (green) and TI cells expressing rat podoplanin (secondary immunofluorescence, red). (J. Vanderbilt, L. Allen, and L. Dobbs, unpublished micrograph.)

We have learned a considerable amount about the biology of TII cells from the study of isolated and cultured TII cells and the development of transgenic mouse models. In contrast, techniques to isolate and study TI cells took many years to develop because of the lack of biochemical or molecular reagents to isolate and evaluate the cells and the fragility of isolated TI cells. Until fairly recently, the accepted concept was that the TI cell was a biologically inactive, terminally differentiated cell. However, recent evidence based on studies of isolated TI cells and gene expression profiling suggests that TI cells play important roles in numerous alveolar functions.

Many published images show only small portions of TI cells because of the large surface area of the cell and limited sampling area of electron microscopy. These images have given rise to an incorrect impression that TI cells do not contain either microvilli or subcellular organelles necessary for biosynthetic and other pathways. In fact, TI cells contain microvilli, abundant mitochondria, Golgi, rough and smooth endoplasmic reticulum, small intracellular vesicles, and caveolae, subcellular domains consistent with both metabolic and endocytic functions (Fig. 8-2).

More detailed analyses of the differences in TI cells and TII cells from both specific studies and gene expression profiling have provided some insight into the functional differences between the two cell types.^{20,21} For example, there are differences in the expression of intercellular junctional proteins. Both TI and TII cells express primarily three claudins (claudin-3, claudin-4, and claudin-18.1).^{22,23} Claudin-3 is associated with decreased barrier function, whereas claudins 4 and 18 are associated with increased barrier function. The proportion of each claudin is different between the two cell types.¹² In TI cells, the lung-specific claudin-18.1 constitutes more than 50% of claudin mRNA, whereas in TII cells, claudin-3 is the dominant claudin. Because TII cells contain approximately 20-fold more claudin-3 protein than do TI cells, it has been suggested that claudin-3 is localized mainly to TI-TII cell junctions and that TI-TII and TI-TI cell junctions may have different paracellular permeability characteristics; for example, it has been proposed

that TI-TII cell junctions are more permeable than the TI-TI cell junctions that constitute the majority of the alveolar epithelial surface.^{12,22} There may be other differences between TI-TI and TI-TII junctions. For example, in models of lung injury, neutrophils appear to migrate across the epithelial barrier selectively between TI and TII cells, although the molecular mechanisms responsible for this apparent selectivity are unknown.^{24,25}

Our concepts about alveolar fluid homeostasis have evolved over the past 10 years. Studies of clearance of exogenously added lung liquid demonstrate rapid clearance of liquid from the alveolar space, suggesting that clearance is mediated by Na^+ channels with a high conductance and/or large numbers of channels with a lower conductance. Ions are transported actively, with water following passively. The osmotic water permeability of TI cells is one of the highest found in mammalian cell membranes, suggesting that TI cells play a major role in passive water transport.²⁶ Presumably aquaporin 5, which is localized in the apical plasma membrane of TI cells,²⁷ is responsible for the high osmotic water permeability; the molecular basis for water transport across the basal surface remains unknown.¹⁴ TI and TII cells also differ in the content of certain ion channels. Studies with either freshly isolated TI and TII cells²⁸ or TII cells cultured under special conditions²⁹ demonstrated that both cell types contain high-conductance sodium channels. TI cells, unlike TII cells, contain *cyclic nucleotide gated* (CNG) channels and K^+ channels, and TII cells contain more *cystic fibrosis transmembrane conductance regulator* (CFTR) than do TI cells per unit area.²⁸ By immunohistochemical methods and Western blotting, TI cells contain the *epithelial sodium channel* (ENaC) and various subunits of the Na^+ , K^+ -ATPase.³⁰ In addition to high-conductance sodium channels, both cell types contain less selective Na^+ channels, although these are far less abundant.²⁸ In most species, less than half of fluid transport in the lung is inhibitable by amiloride^{31,32}; thus, it has been postulated that the amiloride-insensitive CNG channels are responsible for the bulk of transport. The importance of amiloride-insensitive sodium transport was recently reviewed by O'Brodovich and associates.³³ Although patch clamping data are consistent with the presence of CNG channels in TI cells but not TII cells, the presence of CNG channels in TII cells cannot be definitively excluded.

Whereas, in the adult, the epithelium from the alveolus to the nose is, in general, a sodium absorbing epithelium, in utero the alveolar epithelium actively secretes chloride into the developing airspace.^{8,34} Chloride secretion in the adult alveolar epithelium has not been clearly established and probably varies depending on microenvironmental conditions. However, human alveolar epithelial cells in vitro can be stimulated to secrete chloride.³⁵ Both TI cells (CFTR, $\text{Cl}^-/\text{HCO}_3^-$ anion exchanger, and voltage-gated Cl^- channels) and TII cells (CFTR) contain Cl^- channels, and TI cells have been shown to transport Cl^- .³⁶ In addition, the TII cell has a proton sodium exchanger that is likely important in acidifying alveolar fluid.^{8,37}

The pump linked to active sodium resorption is the Na^+ , K^+ -ATPase. It has been estimated that approximately 60% of unstimulated fluid transport in the lung is mediated through the $\alpha 2$ subunit of Na^+ , K^+ -ATPase, which is expressed in TI cells but not in TII cells.³⁸ Data at present

Figure 8-2 Alveolar septum and TI cells. **A**, Low magnification electron micrograph showing the alveolar area of the lung. A TI cell is in the center of the image; from the perinuclear area (N), thin cytoplasmic extensions (arrows) cover the alveolar surface. TI cells contain mitochondria (M) and abundant Golgi apparatus (G). Erythrocytes (R) can be seen in capillaries. Opposing arrowheads delineate the width of an extension of a different TI cell. **B**, The cytoplasmic extensions (arrows) of two different TI cells form a tight junction (boxed area). **C**, Higher magnification of the boxed area in panel B showing more detailed ultrastructure of the tight junction (TJ). **D**, Higher magnification view of a different TI cell showing mitochondria (M), flasklike membrane invaginations typical of caveolae (arrow, C) and other endocytic structures (arrowheads). **E**, Anatomic detail of the air-blood barrier, with thin extensions of a TI cell (TI, arrows) and an endothelial cell (endo, arrow) and the common basement membrane (BM) between the endothelial and epithelial compartments. The capillary contains erythrocytes (RBC). (Lennell Allen and L. Dobbs, unpublished micrographs.)

Table 8-1 Ratios of Various Transport Parameters in TI and TII Cells

	TI:TII Cell Ratio	References
Cell surface area	43	4
Osmotic water permeability	7	26
Na ⁺ and K ⁺ uptake/μg protein	≈3	30
Apical Na ⁺ channels/cell	≈40	28
CNG and K ⁺ channels	*	28
CFTR	6	28

*Present in TI cells, not TII cells.
CFTR, cystic fibrosis transmembrane conductance regulator; CNG, cyclic nucleotide gated.

support the hypothesis that ions and water are transported across the entire alveolar epithelium. Taken together, the large discrepancy in surface area between the cell types, the channel density per unit area (Table 8-1), the likely central role for CNG channels, and the relative importance of the $\alpha 2$ subunit of Na⁺-, K⁺-ATPase all suggest that the TI cell, rather than the TII cell, plays the major role in bulk fluid transport in the alveolar region.

The innate immune functions of TII cells have been well documented, but it is only recently that TI cells have also been shown to have potential immunomodulatory functions.³⁹ TI cells produce proinflammatory cytokines such as TNF- α , IL-6, and IL-1 β after treatment with *lipopolysaccharide* (LPS).⁴⁰ The production of cytokines in TI cells appears to be modulated by the renin-angiotensin system.⁴⁰

TI cells appear to be more susceptible to acute lung injury than are TII cells,⁴¹ and their cellular repair processes are relevant to restoring lung function after injury. TI cells contain abundant caveolae (see Fig. 8-2D) and express caveolin-1.⁴² Caveolae have diverse functions including endocytosis and membrane trafficking,⁴³ and, in addition, they are believed to play an important protective role by providing a source of membrane to protect against cellular lysis. Recent studies of TI cells injured *in vitro* have confirmed that membrane repair by lipid recruitment is facilitated by the caveolar endocytic pathway and by the remodeling of the actin cytoskeleton close to the site of wounding.^{44,45}

On the basis of studies in animal models of lung injury, it has been believed that the injured alveolar epithelium is repaired by proliferation and transdifferentiation of TII cells to TI cells, with TI cells regarded as terminally differentiated cells without proliferative potential.^{46,47} However, on the basis of recent *in vitro* studies, cultured TI cells have been shown to have a high proliferative potential.^{48,49} Both the potential proliferative capacity and phenotypic plasticity of the TI cell *in vitro* raise the possibility that TI cells *in vivo* may participate in lung repair after injury.

Some researchers have stressed the concept that pulmonary epithelium in the conducting airways can sense the environment (e.g., oxidant gases, cigarette smoke, nanoparticles) (see Chapter 10). If this is also true in the alveolus, then it likely that the TI cells, which cover nearly all the alveolar surface, will be shown to be important sensors of the environment.

ALVEOLAR TYPE II CELLS

TII cells were first comprehensively described by C. C. Macklin before the advent of electron microscopy.⁵⁰ Many of his initial predictions about the function of these cells have been verified over the past 60 years. In electron micrographs, TII cells are readily identified by the presence of lamellar bodies, the intracellular storage form of pulmonary surfactant (Fig. 8-3). The major functions of TII cells include: producing pulmonary surfactant, serving as the progenitor cells for maintaining the alveolar epithelium under normal circumstances and after mild injury, transporting fluid to keep the alveoli from flooding, and playing an important role in innate immunity. The high density of mitochondria and high glucose and oxygen consumption indicate that TII cells are highly metabolic. Because TII cells are the only source of surfactant, which is rich in phospholipids, lipid metabolism of the TII cells has been studied extensively.⁵¹ TII cells are highly enriched in genes involved in lipid synthesis.^{52,53} For example, TII cells can be identified in the lung by expression of two enzymes of lipid metabolism, fatty acid synthase and stearoyl CoA desaturase-1, as well as by expression of the traditional markers such as *surfactant protein* (SP) C.⁵² Lipogenesis is upregulated at the end of gestation and is regulated by the transcription factors sterol regulatory element binding protein-1c and CCAAT/enhancer binding protein (C/EBP) alpha, similar to other lipogenic cells.^{52,54} TII cells also are unique in expression of one of the surfactant proteins, SP-C, and the promoter for SP-C has been extremely useful for expressing or deleting genes in murine TII cells. However, while the TII cells express other surfactant proteins, SP-A, SP-B, and SP-D, these proteins are also expressed in nonciliated bronchiolar cells (club cells [Clara]) and at low levels in some extrapulmonary issues.^{55,56}

The turnover of TII cells in the normal, uninfamed lung is relatively slow. However, in response to injury to TI cells, TII cells proliferate rapidly to restore the epithelium. These TII cells become a transit-amplifying population.⁵⁷ The initial studies to demonstrate this relationship used oxidant injuries in rodents to identify the proliferating cells with titrated thymidine.⁵⁸⁻⁶² In these studies, there was an initial labeling of TII cells and, with time, the labeled cells differentiated into TI cells. More recently, the ability of TII cells to proliferate and transdifferentiate into TI cells was documented by lineage tracing techniques in mouse lung.⁴⁶ This recent report demonstrated that TII cells are the source of new TI cells and TII cells under normal conditions and under conditions of mild injury. Hence, TII cells can serve as a transient proliferating cell population to maintain the alveolar epithelium under normal circumstances. However, in response to severe injury such as after influenza or toxins specific to TII cells, other epithelial cells from the bronchioalveolar junction or terminal airways that express keratin V, α_6/β_4 integrin, or club cell secretory protein (Clara), can proliferate, migrate, and, in some circumstances, express SP-C.⁶³ These additional pathways have been reported in mice and, although they are not fully defined, may be important in ARDS. Although the precise regulation of the transition of the TII cell to TI cell phenotype is not known, bone morphogenic protein 2 and *transforming growth factor- β 1* (TGF- β 1) have been suggested as regulators of the TII cell

Figure 8-3 Alveolar epithelial TII cells. **A**, A portion of a TII cell, showing lamellar bodies, a portion of a tight junction (TJ, arrow) between TI and TII cells, and a lamellar body undergoing exocytosis. **B**, Alveolar epithelium showing a TII cell bridging two different alveolar surfaces (arrows) and the perinuclear region of a TI cell. **C**, A portion of a TII cell and secreted lamellar bodies and tubular myelin (TM) in the alveolar space. **D**, A portion of a TII cell with lamellar body (LB) and a composite body (CB). (Lennell Allen and L. Dobbs, unpublished micrographs.)

to TI cell transdifferentiation in vitro.⁶⁴ Keratinocyte growth factor and hepatocyte growth factor are also important mitogens for TII cells in vivo and in vitro.^{65-71,71a}

As stated earlier, alveolar TII cells can also transport sodium and chloride to help maintain alveolar fluid volume.^{72,73} This apical to basal surface fluid transport was first shown in vitro by the formation of *domes*, collections of fluid under the cells that lifted them up into a domelike structure.^{72,73} Under normal circumstances, TII cells resorb fluid by transporting sodium through amiloride-sensitive and amiloride-insensitive sodium channels, thereby keeping the alveolus relatively free of fluid.³³ However, under certain in vitro conditions, TII cells can also *secrete* chloride.³⁵ Unfortunately, defining the precise transport functions of

alveolar TII cells in vitro is compromised by the fact that the culture conditions employed to study transport do not maintain the TII cell phenotype, as determined by the loss of expression of cell differentiation-specific markers, such as the surfactant proteins.

Alveolar TII cells are also important in the initial innate immune response to environmental insults, such as air pollutants, toxins, bacteria, and viruses. Alveolar TII cells are part of the first responders when microbes and other toxic agents enter the alveolus. *Surfactant proteins A* and *D* (SP-A and SP-D) are important components of the innate immune system and are discussed in detail later in this chapter. SP-A and SP-D are multivalent *lectins* (i.e., proteins that bind to carbohydrates and can play numerous roles in biologic

recognition). Indeed, SP-A and SP-D can bind to a variety of viruses, bacteria, and fungi. However, TII cells can also be the target of specific respiratory viruses such as SARS-CoV and influenza.^{74,75} For example, if influenza is instilled into excised human lung, it mainly infects TII cells and does not infect TI cells.⁷⁶ In response to viral infection, TII cells secrete a variety of cytokines to activate macrophages, recruit monocytes, and trigger the adaptive immune system.⁷⁵ The dominant interferon produced by TII cells is interferon- λ (IL29), a type III interferon. The overall magnitude of the cytokine response is robust and similar to the response in alveolar macrophages. The major cytokines produced in response to influenza include CXCL10, IL6, RANTES, and IL29.⁷⁵ Microbes can be recognized by *pathogen recognition receptors* (PRRs), such as *Toll-like receptors* (TLRs). At the mRNA level, human TII cells have significant expression of TLR2, TLR3, and TLR5 but low expression of TLR4 and TLR7, similar to that in bronchial epithelial cells.⁷⁵ TII cells can also respond to *danger-associated molecular patterns* (DAMPs).⁷⁷

TII cells are thought to be important in various lung diseases.⁷⁸ In ARDS and models of acute lung injury, TII cells can repair the alveolar epithelium, although it is possible that other cell populations also participate in this process during severe injury.⁷⁹ TII cells are necessary for restoring the surfactant system, which is critical for gas exchange and for minimizing transudation of fluid into the alveolar space. In interstitial lung disease, TII cell hyperplasia is a common pathologic feature. One of the current hypotheses on the pathogenesis of *idiopathic pulmonary fibrosis* (IPF) is that the fibrotic response is caused by TII cell dysfunction due to protein misfolding and *endoplasmic reticulum* (ER) stress, which ultimately leads to secretion of TGF- β and other profibrogenic factors.^{80,81} Although some have considered an *epithelial mesenchymal transition* (EMT) to be an important part of the fibrotic response, this is unlikely to be important on the basis of recent lineage tracing studies.⁴⁷ Mutations of SP-A and SP-C are thought to cause some types of familial pulmonary fibrosis, and this is thought to be due to protein misfolding and endoplasmic reticular stress.⁸²⁻⁸⁶ Potentially more will be learned about the role of TII cells in interstitial lung disease when these cells are isolated from diseased lung. Finally, TII cells can be a source of adenocarcinomas.⁸⁷ Bronchioalveolar carcinomas and some adenocarcinomas likely arise in TII cells. Surfactant proteins and the transcription factor TTF1 have been used to differentiate lung adenocarcinomas from extrapulmonary sources and the presence of micrometastases in regional lung nodes in staging adenocarcinomas. In the mouse, urethane adenomas all express SP-C, which indicates that they are of TII cell origin⁸⁸ and adenocarcinomas induced by KRAS mutations are also of TII cell origin.⁸⁹

PHYSIOLOGIC FUNCTIONS OF PULMONARY SURFACTANT

The discovery of pulmonary surfactant came from direct physiologic observation and an understanding of the Laplace relationship for calculating surface tension. In 1929, von Neergaard⁹⁰ discovered that there was a differ-

Figure 8-4 Air and saline volume-pressure curves. This figure depicts the classic physiologic observation that led to the discovery of surfactant. It takes more pressure to inflate the lung with air than with saline. However, the pressure difference is much less than would be expected if the alveolar lining had the same surface tension as other biologic fluids, which indicates the presence of a surface active material. The descending limb of the air volume-pressure curve is very reproducible and is used to estimate the surface tension of the lung and static compliance. (Adapted from Radford EP Jr: Recent studies of mechanical properties of mammalian lungs. In Remington JW, editor: *Tissue elasticity*. Washington, DC, 1957, American Physiological Society, pp 177–190.)

ence in the elastic recoil properties of the lung depending on whether the lung was inflated with air or saline so that it took more pressure to inflate a lung with air than with saline (Fig. 8-4). Even though it takes more pressure to inflate the lungs with air than with saline, von Neergaard⁹⁰ calculated that the pressure needed to inflate the lungs with air was much less than expected at low lung volumes. From these observations, von Neergaard deduced that the surface tension in the lung was low.⁹⁰ By studying extracts of lung, Clements and Pattle^{91,92} independently demonstrated that surfactant, specifically the phospholipids of surfactant, was responsible for lowering the surface tension. The low surface tension, produced by pulmonary surfactant, markedly decreases the work of breathing, prevents alveolar collapse and atelectasis, allows for alveoli of different size (radius of curvature) to be stable, and prevents alveolar flooding. Soon after these discoveries, Avery and Mead demonstrated that a deficiency in surface-active material caused NRDS.⁹³ The critical component of surfactant that provides the low surface tension is *dipalmitoylphosphatidylcholine* (DPPC). This is an unusual species of phosphatidylcholine in that both fatty acids are saturated. DPPC molecules can pack closely together and allow the surface monolayer to withstand the high film pressures required to produce a low surface tension at low lung volumes.^{93a}

Film pressure is the pressure required to maintain a surface film and is easiest measured and conceptualized in a Langmuir-Whilhem balance in which a moveable barrier is used to compress a surface monolayer. Compression of the surface balance reduces the area of the surface film similar to exhalation. Surfactant produces a stable film and is able to withstand high film pressures without collapsing. During inflation, surfactant must be absorbed into the surface. During deflation, as the surface area decreases, the film pressure rises and the surface tension falls.

Phospholipid molecules already present in the air-liquid interface get packed closely together. High film pressures squeeze some components of the film, such as unsaturated phospholipids and the surfactant proteins, out of the monolayer. The surface film generated at low lung volumes is thought to be composed of nearly pure (95%) DPPC.⁹⁴ Epi-fluorescence studies with hydrophilic markers have shown that, as the film is compressed, there are areas from which aqueous markers are excluded. Fixation of the lung with osmium vapors has shown that some of the alveolar surface is covered with multilayers of phospholipids, which serve as a reservoir of surfactant to enter the film at high lung volumes. The surfactant system provides a low surface tension in the alveoli and small airways but not in the large airways or trachea.^{95,96}

There are four surfactant-associated proteins, each of which has different functions. From *in vitro* studies on film formation, it is clear that SP-A, SP-B, and SP-C can increase the rate of delivery of phospholipids to the air-liquid interface; by itself, DPPC has an extremely low rate of adsorption to the surface. In addition, SP-A and SP-B were found to be necessary for the formation of tubular myelin (Fig. 8-5).⁹⁷ Tubular myelin is a unique extracellular form of surfactant, in which an organized lattice of surfactant bilayers is formed. These bilayers appear to form at right angles in both transmission electron micrographs and freeze fracture images.¹¹ Tubular myelin is the form of surfactant intermediate between the lamellar body, which is secreted, and the surface monolayer. Tubular myelin is a major component of large-aggregate surfactant, the form that sediments rapidly on centrifugation and is surface active. However, because SP-A-deficient mice lack tubular myelin and have normal respiratory mechanics, the formation of tubular myelin is not absolutely necessary for surfactant function.⁹⁸

Figure 8-5 Tubular myelin. Pulmonary surfactant forms a unique three-dimensional structure composed of phospholipids and the surfactant proteins SP-A, SP-B, and presumably SP-C. Tubular myelin is found only extracellularly and is thought to represent a reservoir of surfactant that can rapidly adsorb into the air-liquid interface. Tubular myelin is isolated as a component of large aggregate surfactant, which is the fraction that sediments readily and is most surface active. (Electron micrograph courtesy Mary Williams, Boston University.)

The major physiologic function of surfactant is to lower surface tension and thereby provide alveolar stability, but surfactant has other functions as well.⁹⁹ Surfactant is important for maintaining the patency and stabilization of small airways.^{100,101} Studies in narrow fluid-filled tubes have demonstrated the critical importance of low surface tension and the need for added surfactant to reduce opening pressures. For this reason, surfactant is important in asthma, constrictive bronchiolitis, and other diseases of small airways. Finally, there is compelling evidence that SP-A and SP-D play important roles in host defense (see later).^{102,103}

COMPOSITION AND POOL SIZES

The critical components of purified surfactant are DPPC, unsaturated phosphatidylcholine, phosphatidylglycerol, and the surfactant proteins (Table 8-2).¹⁰⁴ In a variety of species, the quantity of saturated phosphatidylcholine is related to the alveolar surface area.¹⁰⁵ Phosphatidylglycerol is an anionic phospholipid that is thought to be important in the electrostatic and calcium-dependent interactions with the surfactant proteins. In lung injury, a reduction in the percentage of phosphatidylglycerol is the earliest and most sensitive alteration in the composition of surfactant. Recently, pure phosphatidylglycerol liposomes have been reported to have antiviral properties.¹⁰⁶ However, the phosphatidylglycerol found in mixed micelles with other phospholipids in natural surfactant likely does not have significant antiviral properties. The mechanism by which pool sizes of surfactant are regulated is not understood. However,

Table 8-2 Composition of Pulmonary Surfactant

PHOSPHOLIPIDS: 85%*	% OF PHOSPHOLIPIDS
Phosphatidylcholine	76.3
Dipalmitoylphosphatidylcholine	47.0
Unsaturated phosphatidylcholine	29.3
Phosphatidylglycerol	11.6
Phosphatidylinositol	3.9
Phosphatidylethanolamine	3.3
Sphingomyelin	1.5
Other	3.4
NEUTRAL LIPIDS: 5%†	
Cholesterol, free fatty acids	
PROTEINS: 10%‡	
SP-A	++++
SP-B	+
SP-C	+
SP-D	++
Other	

*The phospholipid composition is constant in most mammalian species.

Unsaturated phosphatidylcholine represents about two thirds of the total phosphatidylcholine. Dipalmitoylphosphatidylcholine makes up the majority species of the disaturated phosphatidylcholine fraction and is the critical molecule for providing the low surface tension.

†There is about 5% neutral lipid, most of which is cholesterol and free fatty acids. There is relatively little triglyceride and cholesterol ester.

‡The composition of the surfactant proteins is not known precisely, but on a mass basis there appears to be more SP-A than SP-D and more SP-A than SP-B and SP-C. However, there is significant uncertainty about the exact values for SP-B and SP-C.

Figure 8-6 Structural organization of surfactant proteins A and D (SP-A and SP-D). SP-A (top) and SP-D (bottom) are collagenous glycoproteins with four important domains. The amino-terminal region contains cysteines for intermolecular disulfide bonding to form covalent oligomeric units. The collagen-like domain imparts structural rigidity and elongated molecular structure to both proteins. In SP-A, the collagen region has a kink, which accounts for the bend in the collagen region and the bouquet-like structure of the octadecamer. In SP-D, the collagen domain is straight and allows formation of a cross-shaped dodecamer. The neck contributes to the trimeric assembly of polypeptide subunits and spacing for the terminal carbohydrate recognition domain (CRD). The CRD is a globular region of the molecule that plays a major role in the recognition of multiple ligands. In SP-A, the CRD accounts for most of the binding to dipalmitoylphosphatidylcholine vesicles, TII cells, macrophages, and inhaled organisms. In SP-D, the CRD unit is responsible for all the reported interactions with viruses and bacteria. (Adapted from Kuroki Y, Voelker DR: Pulmonary surfactant proteins. *J Biol Chem* 269:25943–25946, 1994.)

recently it has been suggested that the TII cell senses the pool of surfactant via SP-D and the orphan receptor Hepta/GPR116.¹⁰⁷⁻¹⁰⁹ A major physiologic regulator of surfactant pool size is clearance by alveolar macrophages as discussed later in this chapter and in Chapter 70.

SURFACTANT PROTEIN A

SP-A was the first surfactant protein identified by its association with surfactant phospholipids (Fig. 8-6). SP-A is a large octadecameric protein with a molecular mass of about 650 kDa.^{110,111} SP-A is a collagenous glycoprotein with a complex, highly ordered tertiary structure. The overall organizational structure of SP-A is similar to serum mannose-binding lectin and the complement component C1q. These molecules form a polarized bouquet-like structure composed of 18 monomers that are organized as six trimeric units. The C-terminal *carbohydrate recognition domain* (CRD) is critical for most SP-A functions and consists of a globular domain that binds carbohydrate and other ligands recognized by SP-A. The structure of the CRD is highly conserved in this class of calcium-dependent lectins. The macromolecular structure of SP-A is 20 nm from the N-terminal to the C-terminal CRD unit and across the array of CRD units. The crystal structure has revealed a hydrophobic binding pocket in the CRD that likely accounts for the lipid binding properties of SP-A.¹¹²

SP-A is localized primarily in the gas-exchange units of the lung and small airways. In rodents, SP-A is found in

alveolar TII cells and also in nonciliated bronchiolar cells (club cells) that line the conducting airways. In humans almost all the SP-A is found in the alveoli, and little is found in the respiratory pseudostratified epithelium that lines the conducting airways. However, there is SP-A in human tracheal submucosal glands.¹¹³

The gene for SP-A is located on chromosome 10 near the closely related proteins, SP-D and mannose-binding lectin. Humans have two genes for SP-A, which code for proteins with minor amino acid alterations in the collagen domain.¹¹⁴ Newly synthesized SP-A undergoes a variety of posttranslational modifications that include proteolytic removal of the signal peptide, addition of N-linked carbohydrates, sialylation, acetylation, and sulfation. Secreted SP-A is highly glycosylated, whereas most of the intracellular form of SP-A is not. A number of factors have been reported to increase the synthesis of SP-A, including cyclic adenosine monophosphate (AMP), keratinocyte growth factor, and interleukin (IL)-1. Corticosteroids produce a biphasic dose response with stimulation at low concentrations and inhibition at high concentrations.

SP-A is secreted from TII cells by two different routes. The dominant route is by direct constitutive secretion independent of exocytosis of the lamellar bodies.^{115,116} In addition, there is secretion of SP-A contained within lamellar bodies. Directly secreted SP-A is newly synthesized, whereas the SP-A found in lamellar bodies is likely derived from recycled SP-A.

In vitro the functions of SP-A include lipid binding and formation of tubular myelin, acceleration of the adsorption of surfactant to the air-liquid interface, and inhibition of surfactant secretion. However, the physiologic importance of these in vitro observations on surfactant regulation has been seriously questioned because the SP-A-deficient mouse has normal surfactant function.^{98,117} More than 99% of SP-A in lavage fluid is bound to phospholipid.^{118,119} SP-A may also be important for maintaining the function of surfactant during acute lung injury, when a variety of serum factors can inhibit surfactant function; SP-A partially inhibits these effects.

However, the major function of SP-A appears to be in innate immunity; SP-A binds to a variety of microorganisms, promotes their clearance by phagocytic cells, and directly alters the function of immune effector cells.^{102,120,121} SP-A, like SP-D, is a multivalent pattern recognition molecule and binds to a wide variety of glycoproteins and other ligands. Because the binding is somewhat promiscuous with a low affinity, the physiologic effects of SP-A are likely due to its polyvalent structure and multiple binding sites on cells and organisms. It has been proposed that SP-A associated with tubular myelin might be one of the first barriers for host protection; multivalent SP-A could bind both surfactant lipid in alveolar fluid and inhaled organisms or particles.¹²²

SP-A binds to both gram-positive and gram-negative bacteria and is thought to be an important component of host defense. SP-A binds gram-negative bacteria with the rough form of LPS, aggregates these bacteria, and increases phagocytosis and killing.^{123,124} SP-A binds poorly to the smooth variants of *Escherichia coli*. Gram-negative bacteria that colonize the respiratory tract usually display the smooth form of LPS, whereas those that colonize the

gastrointestinal tract display rough forms of LPS. SP-A also enhances the adherence and subsequent phagocytosis of mycobacteria by macrophages. Lipoglycans, especially mannosylated lipoarabinomannan, are important ligands for SP-A on mycobacteria. SP-A also binds to a variety of viruses including influenza and respiratory syncytial virus and likely aggregates extracellular virus, which may inhibit infection.

SP-A has been reported to bind to several receptors on macrophages and to modulate the expression of microbicidal factors, TLR2 and 4, and the clearance of apoptotic cells.^{102,125,126} The binding of SP-A to alveolar macrophages appears to be specific and not seen to other mononuclear phagocytes as Kupffer cells, resident peritoneal macrophages, or peritoneal macrophages.¹²⁷ The studies on direct activation of inflammatory cells are complex and depend on the method of SP-A isolation and the state of the inflammatory cells, especially if they have been primed by a cytokine such as interferon- γ . In addition, for in vitro studies to simulate the in vivo situation, it is important that the effect of SP-A is assessed in the presence of surfactant phospholipids because SP-A may bind surfactant phospholipids with a higher affinity than microbes or inflammatory cells. Finally, some preparations of SP-A may have contained TGF- β , which could account for some anti-inflammatory properties.¹²⁸

SP-A appears to suppress the secretion of inflammatory cytokines by macrophages in the normal lung but enhances cytokine production during infection or lung injury. This is sometimes referred to as the *inflammatory paradox* of SP-A. Gardai and colleagues¹²⁹ formulated an interesting mechanism for these observations. In the normal setting, SP-A interacts with macrophages via its CRD domain and binds to signal-inhibitory regulatory protein α , which suppresses cytokine production. However, during infection, SP-A binds the invading organism with its CRD domain and instead interacts with macrophages via its N-terminal domain and binds to the calreticulin/CD91 complex to stimulate the production of inflammatory cytokines. Hence, SP-A can both stimulate and inhibit inflammatory cytokine production in vitro. It is important to recall that in vivo there is a complex interaction among SP-A, the phospholipids of surfactant, inhaled microbes, and receptors on inflammatory cells. Each has a different binding affinity for SP-A and independent regulation. Finally, SP-A has also been shown to bind to apoptotic cells and increase their uptake and removal by macrophages,¹²⁵ although SP-A appears to be less important than SP-D in the clearance of apoptotic cells in vivo (see Chapter 12).

Identifying functional cell receptors for SP-A and SP-D has been challenging because both are polyvalent lectins and can bind to a variety of glycoproteins and glycolipids.^{111,130} Receptors for SP-A are presumably on TII cells for surfactant recycling and on macrophages for surfactant clearance and modulation of the innate immune response. There have been several putative receptors on macrophages, including the calreticulin/CD91 complex, signal-inhibitory regulatory protein α , and SP-R210.^{131,132} The major functional receptor for SP-A on TII cells is P63 (CKAP4).^{130,133} Currently, we do not know the precise role of these receptors in normal surfactant metabolism or in disease.

SP-A also serves as a fetal hormone of parturition. Mendelson and colleagues¹³⁴ have suggested that the fetal lung secretes SP-A, which activates fetal macrophages that migrate to the uterine wall, where they produce IL-1 β and initiate labor.

SP-A-deficient mice have demonstrated the importance of SP-A in host defense for viral and bacterial pathogens.¹³⁵⁻¹³⁷ SP-A-deficient mice are more susceptible to infection by a variety of organisms. There are no reported genetic diseases due to the deficiency of SP-A in humans. However, there is a suggestion that mutation in SP-A may contribute to a familial form of pulmonary fibrosis.⁸⁵

In summary, SP-A is bound to pulmonary surfactant phospholipids in vivo and functions primarily in innate immunity and host defense.

SURFACTANT PROTEIN B

SP-B is the only surfactant protein that has been demonstrated to be crucial for surfactant function and is thought to be critical for the adsorption and surface spreading of phospholipids.¹³⁸⁻¹⁴⁰ Mature SP-B is a homodimer composed of two 79 amino acid polypeptide chains linked by disulfide bonds. The monomer has an expected mass of 8.7 kDa and the homodimer 17.4 kDa. Each monomer has five amphipathic helices that interact with the surface of the monolayer but do not span the monolayer. There are three internal disulfide bridges within the monomer (C8–C17, C11–C71, and C35–C46) and an interchain disulfide at C48.

There is one gene for SP-B that is located on human chromosome 2. The synthesis of SP-B is markedly stimulated by corticosteroids in vitro. This protein undergoes extensive intracellular processing before the mature homodimer is formed. Within the ER, the signal peptide is cleaved and a precursor 42-kD species of SP-B is formed. In multivesicular bodies, additional proteolysis removes a 16-kD amino terminal peptide and a 30-kD carboxy terminal peptide. The final processing of SP-B probably takes place within the multivesicular bodies, and the mature SP-B homodimer is formed by the time it arrives in the lamellar body.

SP-B is required for organizing phospholipids in lamellar bodies, for the formation of tubular myelin, and for delivering phospholipids to the alveolar air-liquid interface. SP-B is thought to be important in film formation and in the entry of phospholipids into the surface monolayer when the film is expanded during inspiration. The five amphipathic helices of SP-B are envisioned to lie along the lipid bilayer or surface monolayer.¹³⁸ SP-B interacts with phospholipid bilayers by electrostatic interactions between the polar head groups of the phospholipids and its positively charged amino acids and through the nonpolar faces of the amphipathic helices that interact with the phospholipid acyl chains. SP-B is positively charged and has a preference for interacting with negatively charged phospholipids, such as phosphatidylglycerol. This surfactant protein is squeezed out of the monolayer at moderate film pressures (40 to 45 mN/m) and does not insert directly into the monolayer or lipid bilayers. SP-B can convert lipid vesicles into phospholipid sheets and is likely to be important in moving lipid into the monolayer with each respiratory cycle.

Mice with homozygous null alleles for SP-B die of respiratory insufficiency shortly after birth, and heterozygotes have impaired surfactant function.^{139,141-143} In genetically targeted mice with conditional expression of SP-B, reduction of SP-B below 25% of the wild-type level results in respiratory failure.¹³⁹ As demonstrated in congenital SP-B deficiency in infants and in genetically altered mice, SP-B is absolutely required for the formation of highly structured lamellar bodies.¹⁴²⁻¹⁴⁵ SP-B is secreted exclusively as a component of lamellar bodies, and lamellar body formation may depend on the ability of SP-B to organize and bind two adjacent lipid bilayers. SP-B is found in natural surfactant preparations, although the content may vary from batch to batch and may differ from that found in surfactant isolated from normal animals. SP-B is also found in club cells (Clara), but the function of SP-B associated with club cells is not known. In SP-B deficiency, there is also aberrant processing of SP-C, which results in the secretion of a partially processed 12 kDa form of SP-C.

In summary, SP-B is a hydrophobic protein critical for the function of surfactant, and a total deficiency in SP-B is a cause of respiratory distress in the newborn. This form of respiratory distress is not responsive to surfactant replacement therapy and requires lung transplantation.

SURFACTANT PROTEIN C

SP-C is an extremely hydrophobic protein that is unique to surfactant and alveolar TII cells.¹⁴⁶⁻¹⁴⁸ SP-C is expressed only in the lung and is a highly specific marker for identifying TII cells. However, the precise physiologic function of this protein is not completely understood. The fully processed form of SP-C is a 35–amino acid lipopeptide that has two palmitates attached as thioesters at amino acids C5 and C6. The segment between residues 13 and 28 forms a hydrophobic α -helix containing aliphatic amino acids, mainly valine. This α -helix is the membrane-spanning portion of SP-C and is extremely stable. In most species, there are two positively charged amino acids, lysine at position 11 and arginine at position 12, which appear to be necessary to move the protein from the ER into the Golgi network, where it is palmitoylated. The precise orientation of the palmitates relative to the valine-rich α -helix is not fully resolved, but both regions are probably important for interactions with phospholipid bilayers or monolayers. SP-C can mix with phospholipids and promote spreading and fusion of phospholipids. SP-C inserts into the monolayer and is squeezed out of the surface monolayer only at relatively high film pressures (>55 mN/m). Presumably, SP-C is important in organizing the phospholipids during the respiratory cycle. SP-C is thought to stabilize the surface film and minimize film collapse. Unlike SP-B, SP-C does not appear to interact with SP-A and is not critical for the formation of tubular myelin. SP-C is found in all preparations of natural surfactant, and a recombinant form of SP-C is used in one type of surfactant replacement therapy.

In humans, there is one gene for SP-C that is located on human chromosome 8. Like SP-B, SP-C is synthesized as a larger precursor form of 21 kDa and processed by proteolytic cleavage of both N-terminal and C-terminal fragments. Most of the posttranslational processing has been com-

pleted before SP-C arrives at the lamellar body. There is apparently some interaction between the processing of SP-B and SP-C because, in hereditary deficiency of SP-B, an aberrantly processed 12 kDa form of a precursor SP-C accumulates in TII cells and in alveolar fluid. The SP-C promoter has been an important tool for overexpressing a variety of transgenes in TII cells in mice.

The physiologic role of SP-C is still not completely known. In one strain, SP-C null mice appear normal until about 6 months of age, at which time they develop chronic pneumonitis and air space enlargement.¹⁴⁹ This demonstrates that SP-C is not absolutely necessary for surfactant function. However, in another strain, mice develop chronic pneumonitis sooner, within 3 months.¹⁵⁰ The genetic background and disease-modifying genes are, therefore, likely involved in clinical manifestations of SP-C deficiency and mutations. Some SP-C mutations in humans also produce a misfolded protein that accumulates and causes ER stress in TII cells and a chronic interstitial lung disease.^{151,152} These observations provide the background for investigating genetic variants in SP-C as a cause of idiopathic interstitial lung diseases, which is discussed later.

In summary, SP-C is a hydrophobic protein that inserts into the surfactant monolayer but does not appear to be critical for surfactant function. However, mutations in this protein and total absence can result in interstitial lung disease. This is the one surfactant protein that is restricted to TII cells.

SURFACTANT PROTEIN D

SP-D is a calcium-dependent lectin and an important component of innate immunity.^{102,153-155} Recombinant SP-D has even been proposed as a therapeutic agent in the treatment of pulmonary infections. Serum SP-D is increased in interstitial lung diseases and may predict outcome in lung transplant recipients.¹⁵⁶ In humans, the gene for SP-D is located near the locus of SP-A on chromosome 10. SP-D is a collagenous glycoprotein with a complex but highly ordered tertiary structure (see Fig. 8-6). The primary structure consists of four domains. The N-terminal segment contains cysteines that form interchain disulfide bonds that cross-link subunits to form covalent oligomeric structures. The adjacent collagen-like region promotes the formation of noncovalent trimers, imparts a rigid longitudinal structure to the molecules, and organizes the spatial distribution of the C-terminal CRDs. The coiled-coil motif of the neck contributes to the spatial organization of the CRD domains. The C-terminal CRD domain contains the calcium and carbohydrate binding sites. The crystal structure of the CRD and neck region of SP-D has shown a distinct spatial distribution of the three CRDs, has defined the carbohydrate binding pocket, and has allowed for computer docking studies to demonstrate the importance of specific vinyl hydroxyl groups in sugars for binding.^{157,158} Identical monomers of SP-D assemble as trimers and then combine to form the final dodecamer, a large symmetric cruciform-shaped molecule with a distance of about 100 nm between the terminal CRDs, about five times larger than SP-A. The CRD unit is primarily responsible for the multivalent binding to surface ligands on microorganisms. As in the case of SP-A, the full oligomerization of SP-D appears to play an

important role in maintaining biologic potency that may result from specific spatial cross-linking of ligands, as well as amplification of relatively weak interactions through multiple binding sites.

Conceptually, SP-D should be thought of as a protein distinct from the surfactant system. SP-D binds the phospholipids of surface-active material weakly and is mostly soluble in alveolar fluid. However, SP-D does bind two lipids with carbohydrate motifs, phosphatidylinositol and glucosylceramide, but not phosphatidylcholine. The location of SP-D in the lung also suggests that it is not directly involved with the surfactant system. SP-D is found in ER of TII cells and in the secretory granules of club cells or nonciliated bronchiolar cells but not in lamellar bodies of TII cells or in tubular myelin. SP-D is highly expressed in the hyperplastic TII cells present in interstitial lung diseases. Like SP-A, SP-D is highly expressed in conducting airways of rodents but sparsely in the major conducting airways in humans. SP-D is also present on many other mucosal surfaces.^{56,159}

SP-D is an important host defense molecule and binds a variety of organisms, usually through its CRD domain.¹⁶⁰ In terms of monosaccharide binding, SP-D has a preference for maltose, glucose, and mannose. The binding of SP-D to organisms can be altered by physiologic glucose concentrations, and impaired binding in the presence of glucose may be important in diabetics.¹⁶¹ SP-D binds influenza A, inhibits hemagglutination, and inhibits infection.^{162,163,163a,163b} It is interesting to note that the annual severity of influenza infections is related to the ability of SP-D to bind to the circulating strains of influenza.^{163,164} Strains with less SP-D binding such as the 1918 H1N1 strain and the pandemic 2009 strain are clinically more virulent. Although studies on the interaction of SP-D with viruses have been reported for only a few viruses, it is likely that SP-D binds to many respiratory viruses. SP-D also binds to bacteria and should be considered an important molecule in host defense. SP-D binds both major components of gram-positive cell walls, peptidoglycan, and lipoteichoic acid.^{154,165} SP-D also binds to LPS and gram-negative bacteria with the rough form of LPS and aggregates these bacteria. SP-D also is likely important in defense against fungal infections. SP-D binds to *Aspergillus fumigatus* conidia and histoplasma and enhances their phagocytosis and killing. SP-D also binds to and agglutinates *Saccharomyces cerevisiae*, and the cell wall ligand for binding is β (1 \rightarrow 6) glucan.¹⁶⁶ This binding is inhibited by pustulan, an extremely effective competitive inhibitor of SP-D. SP-D also binds *Alternaria*, a common mold and aeroallergen, and SP-D may be important in clearing a variety of inhaled fungal spores. Finally, SP-D agglutinates *Mycobacterium tuberculosis* but inhibits its phagocytosis by human macrophages. Once in macrophages, SP-D promotes phagosome-lysosome fusion and thereby intracellular killing of mycobacteria.¹⁶⁷

SP-D has been reported to bind to several different receptors on macrophages and to stimulate microbicidal metabolism, as indicated by the production of reactive oxygen species.¹⁰² Rat SP-D enhances oxygen radical production by alveolar macrophages but not peritoneal macrophages.¹⁶⁸ However, there remain concerns that, in the early studies, the stimulation of macrophages by SP-D could be due to endotoxin contamination.¹⁶⁹ SP-D is also involved in the

clearance of apoptotic cells. SP-D binds to apoptotic cells and facilitates their ingestion by macrophages through the calreticulin and CD91 complex.^{125,170}

The phenotype of the SP-D knockout mouse was unexpected from prior in vitro studies. The knockout mouse shows an increase in the extracellular pools of surfactant and an accumulation of large foamy macrophages with excess metalloprotease activity, which results in alveolar wall destruction and subsequent air space enlargement.¹⁷¹ The implications are that SP-D assists in clearance of surfactant and regulates macrophage function. In addition, a large number of apoptotic cells are found in the air spaces and lavage fluid of SP-D null mice, indicating that SP-D has an important role in the clearance of apoptotic cells. SP-D-deficient mice are also susceptible to infection with various microbes, including influenza A virus and *Aspergillus*.^{136,172}

The interactions of SP-D and SP-A with organisms and phagocytic cells are complex, and the clear identification of the receptors for these proteins is awaited in order to sort out apparently conflicting observations. The interaction will be affected by the organism, growth cycle of the organism, phagocytic cell, and state of activation of the phagocytic cell, as well as the source of SP-A or SP-D and the presence or absence of contaminating endotoxin or TGF- β in the surfactant protein preparation.

In summary, SP-D is a host defense protein like mannose binding lectin and should not be considered as part of the surfactant system. The major functions of SP-D are the clearance of heavily glycosylated viruses such as influenza and the removal of apoptotic cells.

SECRETION AND EXTRACELLULAR PROCESSING OF SURFACTANT

Secretion of the phospholipid components of surfactant has been studied extensively (Fig. 8-7).¹⁷³ Turnover studies have demonstrated that the surfactant system is dynamic; 10% to 20% of the surfactant pool is secreted each hour.^{174,175} Secretion requires active extrusion of the lamellar body contents,¹⁷⁶ which involves fusion of the lamellar body limiting membrane with the plasma membrane.⁹⁷ Several different independent pathways for stimulating secretion work through different receptors and signaling mechanisms. In vivo secretion is stimulated by hyperventilation or even a single deep breath or sigh. Stretch is an important physiologic stimulation, which signals exocytosis through an elevation of intracellular calcium that may in part be stimulated by waves of calcium increases in neighboring cells transmitted through gap junctions.^{12,177} In vitro, tetradecanoyl acetate and adenosine triphosphate (ATP) greatly stimulate basal secretion. Agents that stimulate secretion via cyclic AMP-dependent pathways such as β -agonists and cholera toxin stimulate secretion more modestly. In vivo secretion is likely to be highly regulated, and multiple checks and balances may be present so that alteration in one pathway does not alter turnover.

After exocytosis by alveolar TII cells, the secreted lamellar bodies undergo physical rearrangements extracellularly (see Fig. 8-5). The initial change is the conversion from the

Figure 8-7 Metabolic trafficking of surfactant phospholipids. The phospholipids are synthesized in the rough endoplasmic reticulum (RER) of the alveolar TII cell (1). They are transported to the multivesicular bodies (MVB) (2), where the first lamellae are formed. These lamellae increase to form lamellar bodies (LB), which are subsequently secreted by exocytosis (3). The secreted lamellar body unfolds to form tubular myelin (TM) (4) and other large aggregates (LA). These forms adsorb into the expanded surface monolayer (5). This is a critical step for producing a low surface tension in the alveolus. During the respiratory cycle, as the film is compressed during exhalation, the film pressure rises, and a compressed, closely packed monolayer of nearly pure dipalmitoylphosphatidylcholine is formed (6). Material is excluded from the monolayer (7) and forms small aggregates (SA). Some of these aggregates are ingested by macrophages (8), but most are endocytosed for reprocessing by alveolar type II cells (9 and 10).

multilamellar state to tubular myelin (see Fig. 8-7). This requires SP-A, SP-B, and calcium and can be reproduced *in vitro*.⁹⁷ In lavage samples, *large aggregate* (LA) surfactant can be isolated by differential centrifugation. These aggregates contain SP-A and SP-B and are composed of tubular myelin, multilamellar structures, and other loose lipid arrays, which are the expected forms of secreted and unraveling lamellar bodies. LA adsorbs rapidly to the air-liquid interface and can be considered an extracellular reservoir of surfactant. LA can be converted into *smaller aggregates* (SAs), which are much less surface active. These SAs are thought to represent surfactant that has left the air-liquid interface and are available to be taken up by TII cells and reprocessed. The two dominant routes for the catabolism of surface-active material are uptake by TII cells and catabolism by alveolar macrophages.¹⁷⁴ The current estimates are that about 85% of secreted surfactant is recycled by adult TII cells and about 15% is catabolized by macrophages.^{178,179}

Relatively little pulmonary surfactant goes up the mucociliary escalator, and very little enters the bloodstream or lymphatics. Catabolism of extracellular surface-active material is regulated by *granulocyte-macrophage colony-stimulating factor* (GM-CSF) and its ability to activate macrophages.¹⁸⁰ The autoimmune alveolar proteinosis syndrome is caused by an autoantibody to GM-CSF^{181,182}; some pediatric forms of alveolar proteinosis are due to mutations in the receptor for GM-CSF.^{183,184} The extracellular pool of surfactant appears to be regulated predominately by alveolar macrophages. Deficiency in macrophages or inhibition of their state of activation impairs surfactant clearance and leads to the accumulation of surfactant in the alveolar spaces (see Chapter 70 for additional details).

SURFACTANT ABNORMALITIES IN LUNG DISEASE

PRIMARY SURFACTANT DEFICIENCY OF THE NEWBORN

The importance of the pulmonary surfactant system in the pathophysiology of the NRDS was first reported by Avery and Mead in the late 1950s.⁹³ The observation that NRDS was due to a primary surfactant deficiency has been confirmed by the tremendous impact that exogenous surfactant administration has had on infant mortality.^{185,186} The incidence of NRDS varies with gestational age and birth weight. Approximately 15% of infants born between 34 and 37 weeks (<1700 g) develop NRDS, whereas 50% of infants between 30 and 34 weeks (<1500 g) and 70% of those born at less than 30 weeks (<1250 g) develop this disease. These rates may also be influenced by other factors, including race, gender, socioeconomic status, and maternal health.

Even though artificial ventilation and exogenous surfactant have decreased infant mortality, there still exists a major disability rate among the survivors, particularly in the infants of very low birth weight. Amniotic fluid surfactant analysis reliably predicts the risk of NRDS. Pathologic changes typical of NRDS include widespread atelectasis, capillary congestion, micro-hemorrhage, edema, and the presence of hyaline membranes.⁹³

Fujiwara and colleagues¹⁸⁷ reported the first successful use of exogenous surfactant in neonates with NRDS in 1980. Several large clinical trials demonstrated significant improvement in gas exchange, decreased barotrauma, and decreased infant mortality in response to this therapy. Results of these trials have also shown that surfactant administered prophylactically (i.e., before the first breath) is superior to surfactant given after a period of ventilation. These differences were particularly notable in the infants of very low birth weight (<28 weeks of gestational age) and thus, prophylactic treatment is reserved for infants in this group. Otherwise, surfactant should be administered once the diagnosis of NRDS is established, usually within 30 minutes after birth. The usual dose of surfactant administered to these infants is approximately 100 mg phospholipid/kg body weight. Although surfactant therapy is effective for NRDS, approximately 30% of affected infants do not respond to this therapy.

HEREDITARY SURFACTANT PROTEIN B DEFICIENCY

Although most cases of NRDS result from immaturity, there are inherited forms specifically due to SP-B deficiency.¹⁸⁸⁻¹⁹² Associated abnormalities include aberrantly structured tubular myelin, a decreased number of lamellar bodies, and an abnormal processing of the SP-C protein. Regardless of gestational age, affected patients develop respiratory distress in the first few days of life that is refractory to all therapy, including surfactant supplementation. These infants usually die in the first few months of life, unless they receive a lung transplant. Although the most common abnormality involves a 1-bp deletion and 3-bp insertion in codon 121 in exon 4, which results in a premature stop codon, other mutations can also lead to respiratory failure. The heterozygotes, representing about 1 in 3000 individuals in the general population, would be predicted to have about half the SP-B level and might be more susceptible to ARDS. In mice about 20% of wild-type SP-B is required for normal ventilatory function, but more than 50% of SP-B may be necessary to protect against susceptibility to acute lung injury. NRDS also results from other deficiencies in surfactant synthesis and assembly. The most common deficiency is of the *ATP-binding cassette family member A3* (ABCA3), a lamellar body phospholipid transport protein.^{190,191,193-195} *Thyroid transcription factor 1* (TTF-1) deficiency also produces respiratory failure in infancy accompanied by thyroid and neurologic abnormalities.^{196,197}

HEREDITARY SP-C DEFICIENCY AND MUTATIONS

Deficiency of SP-C would not be expected to produce acute respiratory failure. In mice SP-C deficiency causes diffuse nonspecific chronic interstitial pneumonitis over months to years and depends on the genetic strain. A splice site mutation in intron 4 of the SP-C gene produces chronic interstitial lung disease with an autosomal dominant inheritance pattern.^{189,198,199} Recently additional cases of nonspecific interstitial pneumonitis and usual interstitial pneumonitis have been reported with a single gene mutation.²⁰⁰ This kindred also showed an autosomal dominant inheritance pattern. The hypothesis is that the mutations cause a misfolded SP-C protein, which accumulates and produces ER stress and chronic lung disease. The same genetic abnormality may have a variable phenotype, which indicates the importance of other disease-modifying genes.

ACUTE RESPIRATORY DISTRESS SYNDROME

Early descriptions of ARDS suggested that surfactant abnormalities play an important role in the lung dysfunction. Petty and Ashbaugh²⁰¹ recorded abnormal pressure-volume curves in lungs isolated from patients dying of ARDS. Morphologic changes noted in the lung tissue of these patients at autopsy were similar to those of preterm infants suffering from NRDS. The clinical criteria used to diagnose ARDS, including severe hypoxemia, decreased lung compliance, and bilateral infiltrates on chest radiograph, are also similar to those used to diagnose NRDS. As opposed to a primary

deficiency of surfactant, however, ARDS is much more complex, with many different etiologies and an inflammatory cascade resulting in lung injury and alveolar edema. The alveolar epithelium is severely damaged in ARDS, whereas the alveolar epithelium is relatively intact at the onset of NRDS.

Extensive animal studies and several human reports characterizing surfactant alterations in ARDS and acute lung injury have shown a decrease in the percentage of phosphatidylcholine, phosphatidylglycerol, and DPPC and a corresponding increase in phosphatidylinositol, sphingomyelin and, in some cases, lysophosphatidylcholine.²⁰²⁻²⁰⁴ Decreased levels of SP-A and SP-B have also been demonstrated in *bronchoalveolar lavage* (BAL) samples from patients with ARDS, and the surface tension-lowering properties of the isolated surfactant are abnormal.²⁰³ These abnormalities correlated with the severity of ARDS. BAL samples isolated from patients with severe ARDS also show a decrease in LA surfactant and an increase in poorly surface-active SA. In animal models of acute lung injury, there is a severe reduction of surfactant protein gene expression at the onset of respiratory insufficiency.²⁰⁵ With increased alveolar permeability in patients with ARDS, a number of proteins enter the air space and bind surfactant phospholipids and proteins or directly compete with surfactant molecules for space at the air-liquid interface. Interestingly, this nonstoichiometric inhibition of surfactant by plasma proteins can be overcome *in vitro* by increasing the concentration of surfactant. This observation provides rationale for administering large doses of exogenous surfactant to patients with ARDS. Thrombogenic components leaking into the airspace can also coagulate and incorporate surfactant phospholipids into fibrin clots, thereby rendering the surfactant inaccessible to the air-liquid interface. Surfactant inactivation has also been described due to an increase in the neutral lipids, primarily cholesterol. Another mechanism contributing to surfactant dysfunction in ARDS involves the increased conversion of LA into SA. *In vivo* studies have shown that increased tidal volumes, but not respiratory rates or *positive end-expiratory pressure* (PEEP) levels, correlated with an increased conversion of LA into SA²⁰⁶ and with physiologic deterioration. Minimizing these phasic changes in surface area by means of smaller tidal volumes allows surfactant to be maintained in LA forms and results in improved physiologic outcomes.²⁰⁶ These findings are supported by clinical trials demonstrating improved patient outcomes when lower tidal volumes are used in treating patients with ARDS.^{207,208}

Exogenous surfactant administration has been shown to improve oxygenation but not mortality in patients with ARDS.^{209,209a} A few large multicenter clinical trials have evaluated this therapy and have shown disappointing results.²¹⁰⁻²¹² Presumably, the complexity of ARDS is not addressed by administering exogenous surfactant alone.

INTERSTITIAL LUNG DISEASES

In addition to diseases involving acute alveolar inflammation, alterations in surfactant have also been characterized in various interstitial lung diseases. Decreased levels of DPPC and phosphatidylglycerol, increased levels of phosphatidylinositol, and reduced levels of SP-A have been

observed in BAL fluid from patients with IPF.²¹³⁻²¹⁵ The reduction in SP-A in BAL fluid is found in a variety of diffuse interstitial lung diseases. The ratio of SP-A to phospholipid, used to correct for recovery of total surfactant, is reduced in patients with IPF. In addition, Günther and colleagues²¹⁶ demonstrated that biophysical properties of surfactant are impaired in IPF.

SP-A and SP-D have also been measured in serum and may serve as biomarkers of lung disease, especially when alveolar epithelial integrity is compromised. Serum concentrations of SP-A and SP-D are increased in patients with alveolar proteinosis, ARDS, and IPF.^{214,217,218} Measuring SP-A and SP-D in serum might be useful in the diagnosis of alveolar proteinosis because, together with a highly specific image on high-resolution computed tomographic scanning, high levels of SP-A and D might obviate the need for a biopsy. A small subset of patients with familial pulmonary fibrosis has been attributed to SP-C mutations. Most of the cases have a histopathologic diagnosis of nonspecific interstitial pneumonia, but a few have the morphologic features of usual interstitial pneumonia.²⁰⁰ Mutations in the gene coding for SP-A2 have been also reported to be associated with interstitial lung disease and lung cancer.²¹⁹

OBSTRUCTIVE LUNG DISEASES

The role of surfactant as a down-regulator of inflammation and the importance of surfactant in maintaining the openness of conducting airways suggest that surfactant alterations may be important in obstructive lung diseases.^{101,220} BAL samples from patients with asthma showed decreased SP-A levels and a normal phospholipid composition.¹¹⁹ No surfactant alterations have been demonstrated in patients with chronic bronchitis or emphysema.

Cystic fibrosis is characterized by colonization of both gram-negative and gram-positive bacteria and early airway inflammation. Both SP-A and SP-D are reduced in BAL from patients with cystic fibrosis, and the relative deficiency could contribute to bacteria colonization.²²¹

OTHER LUNG DISEASES

Autoimmune alveolar proteinosis has been shown to be a disease produced by an antibody to GM-CSF, which results in decreased macrophage clearance of surfactant (see Chapter 70 for more information).^{181,182} Alveolar phospholipids and surfactant proteins SP-A, SP-B, and SP-D are markedly increased in the BAL from affected patients. Serum SP-A and SP-D are also increased in these patients.^{214,218} Decreased catabolism of surfactant results in an excess accumulation of multilamellated structures within the alveoli. Effective treatment involves removing this material through whole lung lavage and/or treatment with exogenous GM-CSF. Pediatric forms of alveolar proteinosis can be due to alterations in GM-CSF signaling, usually due to alterations in the GM-CSF receptor.^{183,184} Other forms of genetic impairment of macrophage function in mice lead to an alveolar proteinosis syndrome.²²²

The ischemia-reperfusion injury associated with lung transplantation results in alterations in pulmonary surfactant similar to those observed in patients with severe ARDS. Surfactant administered shortly after transplantation and

reperfusion results in improved gas exchange in comparison with non-surfactant-treated lungs. Moreover, when surfactant is administered to donor lungs before storage, longer storage times are tolerated (up to 38 hours) with relatively better physiologic function after reperfusion.

Measurement of SP-A and SP-D in pleural fluid might also be useful to distinguish metastatic adenocarcinoma of the lung from other adenocarcinomas or mesothelioma.²²³ In addition, surfactant protein gene expression can be used to screen for micrometastases in lymph nodes.²²⁴ In mice with pulmonary adenomas, serum SP-D correlates extremely well with tumor size.²²⁵

ACKNOWLEDGMENT

The authors thank Lennell Allen for Figures 1, 2, and 3; Dennis Voelker for the figure on SP-A and SP-D; Mary Williams for the figure of tubular myelin; and Sarah Murrell for administrative assistance.

Key Points

- Alveolar type I epithelial cells cover about 95% of the alveolar surface of the normal lung, are critical for effective gas exchange, participate in transepithelial fluid movement, and play a role in innate immunity.
- Alveolar type II epithelial cells cover about 5% of the alveolar surface in the normal lung, produce pulmonary surfactant, participate in transepithelial fluid movement, are the precursors of type I cells in normal injury and repair, and play a role in innate immunity.
- Pulmonary surfactant allows for the low surface tension in the gas-exchange portions of the lung and prevents atelectasis, decreases the work of breathing, improves oxygenation, and helps maintain patency of small airways.
- Surfactant protein B is the only surfactant protein critical to surfactant formation in vivo.
- Mutations in the genes encoding SP-A, SP-B, and SP-C can lead to parenchymal lung disease.
- SP-A and SP-D are polyvalent lectins (i.e., proteins that bind to carbohydrates) and are thought to be important components of innate immunity. They bind to both microorganisms and inflammatory cells.
- Surfactant replacement therapy in neonatal respiratory distress syndrome improves survival, whereas replacement therapy in acute respiratory distress syndrome improves oxygenation but not survival.

FUTURE DIRECTIONS

INTRODUCTION

This chapter discusses how the distal lung epithelium regulates lung fluid balance by active ion transport mechanisms across both the alveolar and the distal airway epithelium. Both experimental models of pulmonary edema and clinical studies are considered to illustrate how active sodium and chloride ion transport regulate the resolution of alveolar edema. Some of the material in this chapter has been included in recent reviews.¹⁻³

For many years it was generally believed that differences in hydrostatic and protein osmotic pressures (Starling forces) accounted for the removal of excess fluid from the air spaces of the lung. This misconception persisted in part because some experiments that measured solute flux across the epithelial and endothelial barriers of the lung were done at room temperature⁴ and the studies were done in dogs, a species that turned out to have a very low rate of active sodium and fluid transport.⁵ Although the removal of interstitial pulmonary edema by lung lymphatics and the lung microcirculation was known for a long time,⁶ there was no information on how pulmonary edema was removed from the distal air spaces of the mature lung. Insights into the contribution of active ion transport came from experimental studies of the clearance of alveolar fluid in the mature lung and at the time of birth as well as the development of culture systems to study pulmonary epithelial cells.

LUNG EPITHELIAL FLUID ABSORPTION

With few exceptions, the general model for transepithelial fluid movement is that active salt transport drives osmotic water transport. This paradigm is also correct for fluid clearance from the distal air spaces of the lung.^{7,8} The results of several in vivo studies demonstrated that changes in hydrostatic or protein osmotic pressures cannot account for the removal of excess fluid from the distal air spaces. Furthermore, pharmacologic inhibitors of sodium transport can reduce the rate of fluid clearance in the lungs of several different species, including the human lung.⁹ In addition,

there is good evidence that isolated epithelial cells from the distal air spaces of the lung actively transport sodium and other ions, resulting in osmotic water absorption of fluid from the distal air spaces of the lung.

The large surface area of the alveoli favors the hypothesis that most fluid is reabsorbed at the alveolar level, although fluid may be actively reabsorbed across all of the different segments of the pulmonary epithelium of the distal lung. The precise contribution of each anatomic segment in the distal air spaces to fluid reabsorption is not firmly established. The distal airway epithelium is composed of terminal respiratory and bronchiolar units containing polarized epithelial cells that have the capacity to transport sodium and chloride, including ciliated cells and nonciliated cuboidal club cells (Clara). The alveoli themselves are composed of a thin alveolar epithelium (0.1 to 0.2 μm) that covers 99% of the air space surface area in the lung and contains thin, squamous type I cells and cuboidal type II cells.¹⁰ The alveolar type I cell covers 95% of the alveolar surface. The close apposition between the alveolar epithelium and the vascular endothelium facilitates efficient exchange of gases but also forms a tight barrier to movement of liquid and proteins from the interstitial and vascular spaces, thus assisting in maintaining relatively dry alveoli.

Ion transporters and other membrane proteins are asymmetrically distributed on opposing cell surfaces, conferring vectorial transport properties to the epithelium. Physiologic studies of the barrier properties of tight junctions in the alveolar epithelium indicate that diffusion of water-soluble solutes between alveolar epithelial cells is much slower than through the intercellular junctions of the adjacent lung capillaries.¹¹ Large quantities of soluble protein are removed from the air spaces primarily by restricted diffusion, although there is evidence for some endocytosis and transcytosis of albumin across the alveolar epithelium.¹²

EVIDENCE FOR ACTIVE FLUID TRANSPORT IN THE INTACT LUNG

A substantial number of innovative experimental methods have been used to study fluid and protein transport from the distal air spaces of the intact lung, including isolated

perfused lung preparations, in situ lung preparations, surface fluorescence methods, and intact lung preparations in living animals for short time periods (30 to 240 minutes) or for extended time periods (24 to 144 hours). The advantages and disadvantages of these preparations have been reviewed in some detail.⁸

The first in vivo evidence that active ion transport could account for the removal of alveolar edema fluid across the distal pulmonary epithelium of the mature lung was obtained in studies of anesthetized, ventilated sheep.¹³ In those studies the critical discovery was that isosmolar fluid clearance of salt and water occurred in the face of a rising concentration of protein in the air spaces of the lung, whether the instilled solution was autologous serum or an isosmolar protein solution. The initial protein concentration of the instilled protein solution was the same as that of the circulating plasma. After 4 hours the concentration of the protein had risen from approximately 6.5 g/100 mL to 8.4 g/100 mL, whereas the plasma protein concentration was unchanged. In longer-term studies in unanesthetized, spontaneously breathing sheep, alveolar protein concentrations increased to very high levels. After 12 and 24 hours, the alveolar protein concentrations increased to 10.2 and 12.9 g/100 mL, respectively.¹⁴ The overall rise in protein concentration was equivalent to an increase in distal air space protein osmotic pressure from 25 to 65 cm H₂O. Because the epithelial barrier was intact and thus prevented protein leak into the lung, the only way that the protein concentration could have risen was if water had been removed (i.e., absorbed).

Other studies in the intact lung have supported the hypothesis that removal of alveolar fluid requires active transport.¹⁵ For example, elimination of ventilation to one lung did not change the rate of fluid clearance in sheep, thus ruling out changes in transpulmonary airway pressure as a major determinant of fluid clearance, at least in the uninjured lung.¹⁶ Furthermore, if active ion transport were responsible for alveolar fluid removal, then fluid clearance should be temperature dependent. In an in situ rat lung preparation, fluid clearance was inhibited by low temperature.¹⁷ Similar results were obtained in ex vivo human lung studies,⁹ in which hypothermia inhibited sodium and fluid transport.

Additional evidence for active ion transport was obtained in intact animals with the use of amiloride, an inhibitor of sodium uptake by the apical membrane of alveolar epithelium and distal airway epithelium. Amiloride inhibited 40% to 70% of basal fluid clearance in sheep, rabbits, rats, guinea pigs, and mice and in the human lung.¹ Amiloride also inhibited sodium uptake in distal airway epithelium from sheep and pigs.¹⁸ To explore further the role of active sodium transport, experiments were designed to inhibit Na⁺,K⁺-ATPase. It has been difficult to study the effect of ouabain in intact animals because of cardiac toxicity. However, in the isolated rat lung, ouabain inhibited greater than 90% of fluid clearance.¹⁹ Following the development of an in situ sheep preparation for measuring fluid clearance in the absence of blood flow, it was reported that ouabain inhibited 90% of fluid clearance over a 4-hour period.¹⁶ Other investigators also established the likely role of active fluid transport for removal of fluid from the fetal lung.¹⁵

ION TRANSPORT IN ALVEOLAR AND DISTAL AIRWAY EPITHELIAL CELLS

The success in obtaining nearly pure cultures of alveolar epithelial type II cells from rats made it possible to study the transport properties of these cells and relate the results to the findings in the intact lung studies. When alveolar epithelial type II cells were cultured on a nonporous surface such as plastic, they formed a continuous confluent layer of polarized cells after 2 to 3 days.^{20,21} Interestingly, after 3 to 5 days, small domes of fluid could be appreciated below which the substratum was detached by the formation of the domes. The domes were thought to result from active ion transport from the apical to the basal surface, with water following passively, because they were inhibited by the replacement of sodium by another anion or by pharmacologic inhibitors of sodium transport, such as amiloride and ouabain. More detailed information on the nature of ion transport across alveolar type II cells was obtained by culturing these cells on porous supports and mounting them in Ussing chambers and measuring short-circuit current and ion flux under voltage clamp conditions.^{1,20,22,23}

The coordinated role of apical and basolateral sodium transport has been studied in several in vitro studies. Sodium ions that enter the epithelial cells at the apical membrane are pumped out of the cells at the basolateral membrane by the Na⁺,K⁺-ATPase enzyme. Because of the continuous pumping, sodium chemical potential is lower inside the cell. The entry step is passive, and sodium flows down a chemical potential gradient through specialized pathways, where basolateral transport requires energy to move ions against the gradient. Because of the pump activity, potassium electrochemical potential is larger inside the cell, and potassium leaks through the basolateral membrane and is then recycled by the Na⁺,K⁺-ATPase. The pathways for sodium entry into alveolar type II cells are numerous. Amiloride blocked dome formation^{20,21} and decreased short-circuit current in the in vitro studies,²² a finding that supported the critical importance of sodium uptake through an amiloride-sensitive pathway in the apical membrane of alveolar epithelial cells. As already discussed, the efficacy of amiloride as an inhibitor of fluid clearance in the intact lung was demonstrated in several in vivo studies, although the fraction of amiloride-sensitive transport was as low as 40% to 50% in some lung preparations, particularly in the rat and the human lung. The amiloride-insensitive sodium influx may be represented in vivo in part by the Na⁺-glucose cotransport. A detailed discussion of the pharmacologic, biophysical, and molecular bases for fluid clearance across the alveolar and distal airway epithelium is available in other references.^{1,3,24,25}

The role of the alveolar type I cell in vectorial fluid transport in the lung was unknown until recently; investigators have now assessed the potential contribution of the alveolar type I cell to vectorial fluid transport. On the basis of studies in freshly isolated type I cells, it is known that these cells have a high osmotic permeability to water with expression of aquaporin-5 on the apical surface.²⁶ Recent studies of freshly isolated alveolar type I cells from rats demonstrated

that these cells express the Na^+, K^+ -ATPase α_1 - and α_2 -subunit isoforms.^{27,28} In the same study there was evidence for Na^+, K^+ -ATPase α_1 -subunit expression on the basolateral surface of the alveolar epithelial type I cells in situ in the rat lung. In addition, there is evidence for expression of all the subunits of the *epithelial Na^+ channel* (ENaC) in freshly isolated alveolar type I cells, as well as in situ in the rat lung.²⁹ Finally, there is some evidence that Na uptake can be partially inhibited by amiloride in freshly isolated rat alveolar type I cells,²⁴ although definitive studies of cultured, polarized type I cells have not yet been achieved. Recent data demonstrate that the alveolar epithelial type I cells express a multitude of sodium transporting proteins, ENaC, cyclic nucleotide-gated sodium channels, and the Na^+, K^+ -ATPase.³⁰ In addition, the cells express chloride transporters, that is, the *cystic fibrosis transmembrane regulator* (CFTR), and thus have the ion transporters necessary to participate in vectorial ion transport and clearance of alveolar fluid.³¹ The relative contribution of the type I and type II cells to alveolar edema fluid clearance is still unresolved.

The alveolar epithelium constitutes 99% of the surface area of the lung, a finding that suggests that edema fluid from the lung might be removed primarily across the alveolar epithelium. However, it has been demonstrated that the distal airway epithelium also actively transports sodium, a

process that depends on amiloride-inhibitable uptake of sodium on the apical surface and extrusion of sodium through a basolateral Na^+, K^+ -ATPase.^{1,18} Club cells actively absorb and transport sodium from the apical to the basal surface.²⁸ In addition, there are new data on the possible role of CFTR in up-regulating *cyclic 3',5'-adenosine monophosphate* (cAMP) fluid clearance (see “[Regulation of Lung Epithelial Fluid Transport](#)” section). This information provides support for a possible role of distal airway epithelia in fluid clearance, because CFTR is expressed abundantly in distal airway epithelial cells, as well as in alveolar epithelial cells. Thus, even though their surface area is limited, a contribution from distal airway epithelia to the overall fluid transport is probable, especially because cells from the distal airway epithelium primarily transport salt from the apical to the basolateral surface. [Figure 9-1](#) provides a schematic diagram of our current understanding of the location of ion transporters in the distal airway and alveolar epithelium that are responsible for vectorial fluid transport or net distal air space fluid clearance.

There are also new data confirming the importance of ENaC for alveolar fluid clearance using RNA interference against the αENaC subunit.³² In those studies, inhibition of αENaC expression by specific small interfering RNA against αENaC attenuated the amiloride sensitivity of both normal

Figure 9-1 A schematic diagram of the distal pulmonary epithelium that is relevant for salt and water transport. AQP5, aquaporin-5; CFTR, cystic fibrosis transmembrane regulator; CNG, cyclic nucleotide-gated sodium channel; ENaC, epithelial Na^+ channel. (Modified from Matthay MA, Folkesson HG, Clerici C: Lung epithelial fluid transport and the resolution of pulmonary edema. *Physiol Rev* 82:569–600, 2002.)

and stimulated alveolar fluid clearance, thus demonstrating the importance of ENaC. Finally, there is a newly cloned δ subunit of ENaC that has been identified in human lungs and may play a role in fluid balance in the lung.³³

REGULATION OF LUNG EPITHELIAL FLUID TRANSPORT

This section considers how the rate of vectorial fluid transport across the distal pulmonary epithelium can be increased by catecholamine or cAMP-dependent mechanisms. The potential relevance of these mechanisms under pathologic conditions is evaluated in the section “Alveolar Fluid Transport under Pathologic Conditions,” later in this chapter.

Studies in newborn animals indicated that endogenous release of catecholamines, particularly epinephrine, may stimulate reabsorption of fetal lung fluid from the air spaces of the lung.^{15,34,35} In most adult mammalian species, stimulation of β_2 -adrenergic receptors by either salmeterol, terbutaline, or epinephrine increases fluid clearance.^{5,36–38} This stimulatory effect rapidly follows intravenous administration of epinephrine or instillation of terbutaline into the alveolar space and is prevented by either a nonspecific β_2 -receptor antagonist (propranolol) or, in rats, by a specific β_2 -antagonist.

The increased fluid clearance by β_2 -agonists can be prevented by amiloride or RNA interference against α ENaC, indicating that the stimulation is related to an increased transepithelial sodium transport.^{32,38} In anesthetized ventilated sheep, terbutaline-induced stimulation of fluid clearance was also associated with an increase in lung lymph flow, a finding that reflected increased removal of some of the alveolar fluid volume to the interstitium of the lung.⁵ Although terbutaline increased pulmonary blood flow, this effect was not important because control studies with nitroprusside, an agent that increased pulmonary blood flow, did not increase fluid clearance. Other studies have demonstrated that β -adrenergic agonists increased fluid clearance in rat, dog, guinea pig, and mouse, as well as human lung.¹ The presence of β_1 - and β_2 -receptors on alveolar type II cells has been demonstrated in vivo by autoradiographic and immunochemistry techniques.¹

It has been difficult to quantify the effect of catecholamines on the rate of alveolar fluid clearance and edema resolution in humans.³⁹ However, studies of fluid clearance in the isolated human lung have demonstrated that β -adrenergic agonist therapy increases fluid clearance, and the increased fluid clearance can be inhibited with propranolol or amiloride.⁹ Subsequent studies suggested that long-acting lipid-soluble β -agonists may be more potent than hydrophilic β -agonists in the ex vivo human lung.³⁸ The magnitude of the stimulatory effect is similar to that observed in other species, with a β -agonist-dependent doubling of fluid clearance over baseline levels.⁴⁰ These data are particularly important because aerosolized β -agonist treatment in some patients with pulmonary edema might accelerate the resolution of alveolar edema (see “Alveolar Fluid Transport under Pathologic Conditions” section).

What has been learned about the basic mechanisms that mediate the catecholamine-dependent up-regulation of sodium transport in the lung? Based on in vitro studies, it was proposed that an increase in intracellular cAMP resulted in increased sodium transport across alveolar type II cells by an independent up-regulation of the apical sodium conductive pathways and the basolateral Na^+, K^+ -ATPase. Proposed mechanisms for up-regulation of sodium transport proteins by cAMP include augmented sodium channel open probability,^{1,41} increases in Na^+, K^+ -ATPase α -subunit phosphorylation, and delivery of more ENaC channels to the apical membrane and more Na^+, K^+ -ATPases to the basolateral cell membrane.¹

Although most experimental studies have attributed a primary role for active sodium transport in the vectorial transport of salt and water from the apical to the basal surface of the alveolar epithelium of the lung, the potential role of chloride, especially in mediating the cAMP-mediated up-regulation of fluid clearance across distal lung epithelium, has been the subject of several studies. A study of cultured alveolar epithelial type II cells suggested that cAMP-mediated apical uptake of sodium might depend on an initial uptake of chloride.⁴² A more recent study of cultured alveolar type II cells under apical surface–air interface conditions reported that β -adrenergic agonists produced acute activation of apical chloride channels with enhanced sodium absorption.⁴³ However, the results of these studies were considered to be inconclusive by some investigators,⁴⁴ partly because the data depend on cultured cells of an uncertain phenotype. Type II cells cultured under conditions for studying transepithelial transport are usually studied under conditions that no longer maintain their phenotype as defined by surfactant protein expression. Furthermore, studies of isolated alveolar epithelial type II cells do not address the possibility that vectorial fluid transport may be mediated by several different epithelial cells, including alveolar epithelial type I cells as well as distal airway epithelial cells. The relative contribution of alveolar type I cells and alveolar type II cells to transepithelial transport remains unresolved.³

In order to define the role of chloride transport in the active transport of salt and water across the distal pulmonary epithelium of the lung, one group has used in vivo lung studies to define the mechanisms and pathways that regulate chloride transport during the absorption of fluid from the distal air spaces of the lung.⁴⁵ This approach may be important because studies in several species, as already discussed, have indicated that distal airway epithelia are capable of ion transport and that both ENaC and CFTR are expressed in alveolar and distal airway epithelia.

Both inhibition and ion substitution studies demonstrated that chloride transport was necessary for basal fluid clearance. The potential role of CFTR under basal and cAMP-stimulated conditions was tested using intact lung studies in which CFTR was not functional because of failure in trafficking of CFTR to the cell membrane, the most common human mutation in cystic fibrosis ($\Delta F508$ mice). The results supported the hypothesis that CFTR was essential for cAMP-mediated up-regulation of isosmolar fluid clearance from the distal air spaces of the lung because fluid clearance could not be increased in the $\Delta F508$ mice either

with β -agonists or with forskolin, unlike in the wild-type control mice.⁴⁵ Additional studies using pharmacologic inhibition of CFTR in both mouse and human lungs with glibenclamide supported the same conclusion, namely that chloride uptake and CFTR-like transport seemed to be required for cAMP-stimulated fluid clearance from the distal air spaces of the lung.⁴⁶ Glibenclamide can also inhibit potassium channels, so the inhibitory effects may not be specific for CFTR, but the $\Delta F508$ mouse studies have provided more direct evidence. Although the absence of CFTR in the upper airways results in enhanced sodium absorption, the data in these studies provide evidence that the absence of CFTR prevents cAMP-up-regulated fluid clearance from the distal air spaces of the lung, a finding that is similar to the results from studies on the importance of CFTR in mediating cAMP-stimulated sodium absorption in human sweat ducts.⁴⁷ Because CFTR is distributed throughout the distal airway epithelium, as well as at the alveolar level in the human lung,⁴⁸ the data also suggest that the cAMP-mediated up-regulated reabsorption of pulmonary edema fluid may take place across distal airway epithelium as well as at the level of the alveolar epithelium. Finally, additional studies indicated that the lack of CFTR results in a greater accumulation of pulmonary edema in the presence of a hydrostatic stress, thus demonstrating the potential physiologic importance of CFTR in up-regulating fluid transport from the distal air spaces of the lung.⁴⁵ There is evidence that functional CFTR chloride channels are present in adult rat alveolar epithelial type II cells based on whole cell patch-clamp experiments.⁴⁹ In addition, there is expression of CFTR in both alveolar type I and II cells.^{30,31} A study using a novel CFTR-specific inhibitor, CFTR_{inh-172}, in human lungs again demonstrated the importance of CFTR and chloride transport for cAMP-driven fluid absorption.⁵⁰

In the last few years, several interesting catecholamine-independent mechanisms have been identified that can up-regulate fluid transport across the distal air spaces of the lung as well as in cultured alveolar type II cells. Hormonal factors such as glucocorticoids can up-regulate transport by transcriptional mechanisms, whereas thyroid hormone may work by a posttranslational mechanism. Some growth factors can work by either transcriptional or direct membrane effects or by enhancing the number of alveolar type II cells. For example, keratinocyte growth factor is a potent mitogen for alveolar type II cells. Administration of keratinocyte growth factor (5 mg/kg) into the distal air spaces of the rat lung increases fluid clearance by 66% over baseline levels.⁵¹ Other investigators have shown that keratinocyte growth factor can enhance sodium and fluid transport in normal and injured rat lungs.^{52,53} Keratinocyte growth factor may also work by enhancing the expression of sodium transport proteins.⁵⁴ There is also evidence that a proinflammatory cytokine, tumor necrosis factor- α , can rapidly up-regulate sodium uptake and fluid transport. The effect of tumor necrosis factor- α is amiloride-inhibitable in both rats and isolated A549 human cells.^{55,56} Finally, serine proteases can regulate the activity of ENaC and potentially increase fluid clearance across the distal airway epithelium.⁵⁷ These catecholamine-independent mechanisms are explored in more detail in one review.¹ Recent work has demonstrated that isolated human alveolar epithelial type

II cells have the capacity to absorb sodium by ENaC-dependent mechanisms and secrete chloride by CFTR-dependent pathways. Based on these *in vitro* studies, alveolar epithelial type II cells (1) achieved an extracellular nucleotide concentration-dependent steady state alveolar surface liquid height of approximately 4 μ m *in vitro*, (2) absorbed liquid when the lumen was flooded, and (3) secreted liquid when treated with uridine triphosphate or forskolin or subjected to cyclic compressive stresses mimicking tidal breathing. Collectively these studies suggest that human alveolar epithelial type II cells *in vitro* have the capacity to absorb or secrete liquid in response to local alveolar conditions.⁵⁸

MECHANISMS THAT CAN IMPAIR THE RESOLUTION OF ALVEOLAR EDEMA

Several mechanisms have been identified that can impair fluid transport from the distal air spaces of the lung. This section considers three conditions that have relevance to human disease: hypoxia, the use of anesthetics, and the presence of reactive oxygen and nitrogen species. The next section reviews mechanisms that impair fluid transport under specific pathologic conditions.

Hypoxia may arise during residence or recreation at high altitudes and under a variety of pathologic conditions associated with acute and chronic respiratory disease. Therefore it is important to understand the effect of hypoxia on the ion and fluid transport capacity of the lung epithelium. The effect of hypoxia under *in vivo* conditions has been studied primarily in rats. In anesthetized rats, as well as in isolated perfused lungs, hypoxia decreased alveolar liquid clearance by inhibition of the amiloride-sensitive component.^{59,60} The effect of hypoxia could not be explained by transcriptional effects on ENaC or Na⁺,K⁺-ATPase. The results suggested a posttranslational mechanism such as a direct change of sodium transporter protein activity or transport to the plasma membrane. This latter hypothesis was supported by the normalization of fluid clearance by a cAMP agonist (terbutaline), which appears to increase the trafficking of sodium transporter proteins from the cytoplasm to the membrane.^{61,62} Direct evidence for this mechanism in hypoxic alveolar epithelial type II cells was demonstrated for ENaC²³ as well as for an inhibitory effect of hypoxia on Na⁺,K⁺-ATPase activity in isolated A549 cells.⁶³

In alveolar epithelial cells the halogenated anesthetics affect sodium and fluid transport at the physiologic level as well as on a cellular level. In the rat, halothane and isoflurane decrease fluid clearance by inhibition of the amiloride-sensitive component. This effect was rapidly reversible after cessation of halothane exposure.⁶⁴ *In vitro*, exposure to a low concentration of halothane (1%) for a short time (30 minutes) induced a reversible decrease in Na⁺,K⁺-ATPase activity and amiloride-sensitive ²²Na influx in rat alveolar type II cells.⁶⁵ The mechanisms whereby halothane induced a decrease in sodium transport protein activity have not been yet elucidated, but they are not related *in vitro* to a decrease in intracellular adenosine triphosphate content or

to a change in cytosolic free calcium. Taken together, these observations suggest that halogenated anesthetics may interfere with the clearance of alveolar edema.

Lidocaine is widely used in patients with acute cardiac disorders and has also been recently implicated as a possible cause of pulmonary edema following liposuction. In experimental studies in rats, either intravenous or intra-alveolar lidocaine reduced fluid clearance in rats by 50%.⁶⁶ Because lidocaine did not inhibit ENaC when expressed in oocytes, it seems that the inhibitory effect on vectorial fluid transport was primarily on the basal surface of alveolar epithelial cells, either through an effect on the activity of $\text{Na}^+\text{K}^+\text{ATPase}$ or through an indirect effect via blockade of potassium channels, a well-known property of lidocaine. The effect of lidocaine was also completely reversible with β_2 -agonist therapy.⁶⁶

Under several pathologic conditions, in response to pro-inflammatory cytokines, activated neutrophils and macrophages can localize in the lung and migrate into the air spaces of the lung, and release reactive oxygen species by the membrane-bound enzyme complex nicotinamide adenine dinucleotide phosphate oxidase and *nitric oxide* (NO) via the calcium-insensitive inducible form of NO synthase. NO decreased short-circuit current across cultured rat type II cells without affecting transepithelial resistance. NO also inhibited 60% of amiloride-sensitive short-circuit current across type II cell monolayers following permeabilization of the basolateral membrane with amphotericin B.⁶⁷ NO reacted with superoxide (O_2^-) to form peroxynitrite (ONOO^-), a potent oxidant and nitrating species that directly oxidizes a wide spectrum of biologic molecules, such as DNA constituents, lipids, and proteins.²⁴ Boluses of peroxynitrite (0.5 to 1 mM) delivered into suspensions of freshly isolated type II cells from rabbits decreased amiloride-inhibitable sodium uptake to 68% and 56% of control values, respectively, without affecting cell viability. Some investigators reported that products of macrophages, including NO, can down-regulate sodium transport in fetal distal lung epithelium stimulated with endotoxin.⁶⁸ The data indicate that oxidation of critical amino acids residues in ENaC protein is probably responsible for this effect. This evidence matches well with other studies that have shown that protein nitration and oxidation by reactive oxygen and nitrogen species have been associated with diminished function of a variety of important proteins present in the alveolar space, including surfactant protein A.⁶⁹

There is also evidence that transforming growth factor- β 1 decreases expression of ENaC and alveolar epithelial sodium and fluid transport by an ERK 1/2-dependent mechanism in both primary rat and human alveolar type II cells.⁷⁰

ALVEOLAR FLUID TRANSPORT UNDER PATHOLOGIC CONDITIONS

Fluid clearance from the distal air spaces of the lung has been measured in mechanically ventilated patients with acute respiratory failure from pulmonary edema as well as

in several animal models designed to simulate clinically relevant pathologic conditions.

Studies of fluid clearance have been done in intubated, ventilated patients by measuring the concentration of total protein in sequential samples of undiluted pulmonary edema fluid aspirated from the distal air spaces of the lung with a standard suction catheter passed through the endotracheal tube into a wedged position in the distal airways of the lung.^{39,71,72} This method for measuring fluid clearance in patients was adapted from the method for aspirating fluid from the distal air spaces of the lung in experimental studies in small and large animals.^{5,8} The clinical procedure has been validated in patients by demonstrating that there is a relationship between fluid clearance and the improvement in oxygenation and the chest radiograph.^{39,72}

In patients with severe hydrostatic pulmonary edema, there was net fluid clearance in the majority during the first 4 hours after endotracheal intubation and the onset of positive-pressure ventilation.⁷³ The rate of fluid clearance was 14%/hr in 38% of the patients. Overall, 75% of the patients had intact fluid clearance. There was no significant correlation between the levels of fluid clearance and endogenous plasma levels of epinephrine, although twice as many of the patients with intact fluid clearance received aerosolized β -adrenergic therapy as did those with impaired fluid clearance; this difference did not reach statistical significance, perhaps because the total number of studied patients was modest. In a recent study of congestive heart failure in rats, it was demonstrated that β -adrenergic stimulation increased alveolar fluid clearance and that type II cell hyperplasia might be responsible for the stimulation.⁷¹

The majority of patients with increased permeability edema and *acute lung injury* (ALI) have impaired alveolar epithelial fluid transport, a finding that is associated with more prolonged respiratory failure and a higher mortality (Fig. 9-2). In contrast, a minority of patients can remove alveolar edema fluid rapidly, and these patients have a higher survival rate.^{39,72} These results indicate that a functional, intact distal lung epithelium is associated with a

Figure 9-2 Hospital mortality is increased in patients with acute lung injury (ALI) or the acute respiratory distress syndrome (ARDS) with impaired fluid clearance. Impaired fluid clearance ($<14\%/hr$) was compared with those with maximal fluid clearance ($>14\%/hr$). The columns represent percent hospital mortality in each group. Hospital mortality of patients with maximal fluid clearance was significantly less ($P < 0.02$). N, number of patients. (Data from Ware LB, Matthay MA: Alveolar fluid clearance is impaired in the majority of patients with acute lung injury and the acute respiratory distress syndrome. *Am J Respir Crit Care Med* 163:1376–1383, 2001.)

better prognosis in patients with ALI, thus supporting the hypothesis that the degree of injury to the distal lung epithelium is an important determinant of the outcome in patients with increased permeability pulmonary edema from ALI. There is also new evidence that alveolar fluid clearance in patients with sepsis is inversely related to the severity of shock (number of vasopressors) in patients with ALI.⁷⁴

What are the mechanisms that may impair fluid clearance from the air spaces of the lung in patients with ALI? As already explained, alveolar hypoxia can depress alveolar epithelial fluid transport. Also, viral or bacterial lung infection can depress alveolar fluid transport, either by interfering with normal ion transport or by inducing apoptosis or necrosis of the distal lung epithelium. In addition, a decrease in fluid clearance may be associated with higher levels of nitrate and nitrite in pulmonary edema fluid, a finding that supports the hypothesis that proteins essential to epithelial fluid transport may undergo nitration and oxidation in some patients with lung injury, further depressing their ability to remove alveolar edema fluid.⁶⁹ Further, the receptor for advanced glycation end products may be a marker for alveolar type I cell injury and predict a reduced rate of clearing pulmonary edema fluid.⁷⁵

FUTURE DIRECTIONS

It is possible to quantify the rate of edema reabsorption from the distal air spaces of the lung in ventilated, critically ill patients with acute pulmonary edema. In conjunction with progress in experimental studies of lung fluid balance under clinically relevant pathologic conditions, further studies should be done to test the potential role of catecholamine-dependent and catecholamine-independent therapies that might enhance the resolution of clinical pulmonary edema. Experimental data in a rat model of ALI indicated that β_2 -adrenergic agonist therapy can decrease lung endothelial permeability, increase alveolar fluid clearance, and decrease pulmonary edema when given after lung injury had developed.⁷⁶ The feasibility of delivering therapeutic concentrations of aerosolized β_2 -adrenergic agonist therapy to the distal air spaces of ventilated patients was demonstrated.⁷⁷ However, clinical trials with aerosolized or intravenous β_2 -agonists did not improve clinical outcomes in patients with ALI, perhaps because the injury to the alveolar epithelium was too severe.^{78,79} β_2 -adrenergic agonists may still have a therapeutic role in increasing the rate of alveolar fluid clearance in patients with hydrostatic or cardiogenic pulmonary edema.

Key Points

- The distal conducting airways and alveolar surface are lined with epithelial cells that provide a tight barrier to protect the distal air spaces for gas exchange.
- The primary mechanism for reabsorption of excess alveolar fluid is active vectorial sodium and chloride transport.
- The best-understood transporters are the epithelial Na^+ channel and cystic fibrosis transmembrane regulator.
- The resolution of alveolar edema is driven by active ion transport and can be up-regulated by cyclic 3',5'-adenosine monophosphate stimulation.
- Alveolar fluid transport is impaired in patients with acute lung injury.

MUCUS BIOLOGY: PRESENT STATUS AND FUTURE OPPORTUNITIES

INTRODUCTION

When animals migrated from sea to land, gills were exchanged for lungs, thus increasing the surface area for gas exchange, and the respiratory organ (lungs) was relocated deep within the thorax. This new apparatus required a connection from the areas of gas exchange in the alveoli to the external environment, which was provided by the airways. The airway epithelium is exposed to a wide array of environmental “invaders,” such as bacteria, viruses, allergens, and environmental toxins such as cigarette smoke and air pollutants. Particulate invaders first deposit on the luminal airway epithelial surface and move across the surface to enter the body of the host. In healthy individuals the scarcity of secretions, the effectiveness of clearance of invaders from the epithelial surface, and the efficiency of the host systems for defensive cellular responses to invaders allows protection of the host without symptoms or significant pathologic changes. However, in chronic inflammatory airway diseases, pathologic responses are overexuberant, impairing rather than protecting the host. This chapter focuses on mucus and its major constituent, mucins, and the effects of their hypersecretion.

COMPONENTS OF MUCUS

Mucous secretion normally plays a protective role in the epithelium. Airway mucus is a complex mixture of proteins and liquids and includes a sol phase composed of water and electrolytes.^{1,2} Mucus consists of water (95%), most of which is bound in a viscoelastic gel containing mucins.^{3,4} The gel-forming mucins in mucus are high-molecular-weight glycoproteins that are key components of mucous cells and are rich in carbohydrates.⁵ Mucin oligosaccharides

are joined by an initial α_0 -glycoside linkage of N-acetylgalactosamine to the hydroxyl moieties of serine or threonine of the mucin protein backbone.⁶ Mucins produced intracellularly are packed tightly within granules. During exocytosis the cells secrete their granule contents in a condensed form, and the secreted mucins undergo rapid hydration to form a gel with unusual viscoelastic properties that allow the mucins to interact with cilia to effect mucociliary clearance. Various mucins may have very different biophysical properties, and future studies are needed to characterize these properties and their potential pathophysiologic implications. Currently approximately 19 *mucin* (MUC) genes have been cloned. They are divided into two groups: membrane-associated and gel-forming secreted mucins.^{7,8} Of the secreted mucins, two are especially prominent in inflammatory airway diseases: MUC5AC in airway goblet cells⁹⁻¹² and MUC5B in submucosal gland mucous cells.^{9,10,13,14}

NORMAL AIRWAY MUCINS

Gel-forming mucins are produced by mucous tubules in submucosal glands in the large conducting airways and by goblet cells located in the surface epithelium in both large and small airways. MUC5AC is the predominant mucin produced by the surface epithelium¹⁵ and by airway epithelial cells in culture.^{11,16} MUC5B is the predominant mucin in the submucosal glands.¹⁷ MUC5AC is more susceptible to proteolytic degradation than is MUC5B.¹⁸ Thus mucins have a complicated structure, which is likely to contribute to their functions. In the normal surface epithelium, goblet cells are sparse^{11,19,20} but present at all levels, decreasing in number peripherally, presumably reflecting less contact of peripheral airways with invading environmental particulates. Pathogen-free animals have few goblet cells in the airway

epithelium. In healthy airways, multiple stimuli induce mucin production, but the amount of mucin production is small.

On the surface of the airways is a periciliary sol phase, above which the mucous gel floats. The contracting cilia propel the mucous blanket mouthward, along with trapped environmental particles that have deposited on the epithelial surface.

MUCOUS HYPERSECRETORY DISEASES AND THEIR CLINICAL CONSEQUENCES

DIFFERENCES IN CLINICAL PRESENTATION AMONG VARIOUS HYPERSECRETORY DISEASES

Chronic inflammatory airway diseases are associated with mucous hypersecretion, and the stimuli involved may vary. For example, allergic factors are involved in asthma (see Chapter 41), genetic abnormalities underlie *cystic fibrosis* (CF) (see Chapter 47), and the inhalation of toxic components of cigarette smoke is the main cause of *chronic obstructive pulmonary disease* (COPD) (see Chapter 43). Regardless of the variety of causes, the similarities that exist in cellular responses among these various disease states (including mucous hypersecretion) suggest that some common mechanisms are likely to exist that could be useful in therapy.

In patients with severe asthma,²¹ CF,¹⁹ and COPD,²² exaggerated airway epithelial mucin production can lead to mucous plugging and sometimes to death. MUC5AC contributes importantly to mucous plugging in these diseases.^{9-12,19} In patients with hypersecretory diseases, multiple stimuli can exaggerate mucus production and cause clinical exacerbations. Examples of these stimuli are listed in Table 10-1.

Table 10-1 Examples of Stimuli That Induce Mucin Synthesis In Vitro or In Vivo by EGFR Activation In Airways

MANIFESTATIONS OF MUCOUS HYPERSECRETION DEPEND ON AIRWAY LOCATION

Intrathoracic airways branch continuously from the trachea to small airways (terminal bronchioles) before they finally arrive in the alveolar zone. Because of their peripheral location, the small airways remain relatively “silent.”

In the 1950s, clinicians recognized a clinical condition consisting of cough and sputum production (which they called “chronic bronchitis” or “simple bronchitis”).²³ They recognized the symptoms as part of a disease of the conducting airways that was disturbing to patients but did not cause serious clinical deterioration or death. One logical explanation for this clinical condition was as follows: in disease of the conducting airways, overproduction of mucins in the submucosal glands travels to the airway lumen via ducts localized to airway bifurcations.²⁴ The cough receptors are colocalized at airway bifurcations. Stimulation of these receptors (e.g., by chronic smoking) causes cough and activates mucous secretion (Fig. 10-1).

Together, anatomists and physiologists advanced the structural analysis of mucin production in submucosal glands and in epithelial goblet cells. These innovators paid little attention to the importance of the peripheral airways. However, it was pathologists who became intrigued by bronchiolar mucous plugging and suggested that plugging was an early event in the development of emphysema.²⁵ In the study of mucins, this seminal observation lost out to the interest in mucin studies in the large airways,²⁶ which led to the discoveries of the mucin genes and the signaling pathways involved in mucin production. However, the importance of the small airways soon resurfaced: in 1963 the anatomist Ewald Weibel analyzed the total airway cross

Figure 10-1 Colocalization of gland duct opening and cough receptors at airway bifurcations. Tantalum bronchogram outlines airways. Arrow indicates site of submucosal gland duct opening and site of cough receptor concentration at large airway bifurcation. (From Nadel JA: Mucous hypersecretion and relationship to cough. *Pulm Pharmacol Ther* 26[5]:510–513, 2013.)

section as a function of generation number.²⁷ He showed that the first five generations occupy a small cross-sectional area and that the bronchioles occupy an exponentially increased cross-sectional area (see Fig. 4-2). Using Weibel's data, it was predicted that normally most of the airflow resistance resides in the large airways and that the airflow resistance contributed by the bronchioles is normally very small.

Early studies implicated bronchioles in lung disease, but their study has been impeded because (1) bronchoscopy, which is very useful for examination and biopsy of large airways, is unable to visualize bronchioles; (2) clinical radiologic techniques still cannot resolve bronchioles; and (3) for structural reasons, biopsies are not usually useful in bronchiolar pathologic conditions. For these reasons, bronchioles still remain a relatively “silent zone” of the lungs!

In bronchioles, because of striking differences in structure from the large airways, the effects of mucous hypersecretion have different manifestations. Bronchiolar hypersecretion is not associated with cough because bronchioles do not possess cough receptors. Furthermore, the number of bronchioles and therefore the total cross-sectional area is very large,²⁸ so obstruction of bronchioles will not have a measurable effect on airflow resistance until most of the bronchioles are occluded.²⁹ In acute asthma the importance of bronchiolar obstruction has often only been discovered postmortem, when microscopic examination of bronchioles has shown extensive bronchiolar plugging.²¹ Diffuse bronchiolar plugging is also found in advanced CF at the time of lung transplantation.¹⁹ Remarkably, the potential importance of bronchiolar obstruction was reported as long ago as 1956 by pathologists as an early manifestation of emphysema, but the role of plugging in lung tissue breakdown was not explored.²⁵

Because of the small diameters, bronchioles are more likely to become obstructed (“plugged”) than airways with larger diameters. Therapy for airway obstruction usually focuses on smooth muscle contraction (“bronchospasm”). However, in chronic obstructive airway diseases, thickening of the airway wall and mucous hypersecretion are predicted to contribute significantly to the airflow limitation that is present (shown schematically in Fig. 10-2). In spite of the fact that chronic progressive mucous plugging is common in chronic inflammatory airway diseases such as COPD,²² CF,¹⁹ and acute fatal asthma,^{21,30-33} the clinical detection of peripheral mucous plugging is very difficult. This is due to the fact that these small structures are not visualized radiologically or visually during bronchoscopy and are difficult to sample in biopsies. Novel methods for further examination of bronchiolar structure and function are sorely needed.

IMPORTANCE OF MUCOUS HYPERSECRETION IN CHRONIC INFLAMMATORY AIRWAY DISEASES

In healthy subjects, mucous secretion is involved in innate immune defense of the host (see Chapter 12). These host responses normally defend efficiently against inhaled

Figure 10-2 Schematic representation of the potential impact of goblet cell hyperplasia and mucous plugging on small airway obstruction. In normal individuals the surface epithelium covering small airways (blue) contains few goblet cells and is composed of a thin layer of epithelial cells. **A** and **B**, Normal, thin epithelium contributes little to luminal narrowing both when airway smooth muscles are relaxed (**A**) and when smooth muscles shorten (**B**). **C** and **D**, In various airway inflammatory diseases (e.g., acute asthma, COPD, cystic fibrosis), epithelial cell hyperplasia is present in small airway epithelium, resulting in epithelial thickening. **C**, When airway smooth muscles are relaxed, thickened epithelium may contribute little to airflow limitation. **D**, However, when smooth muscles shorten, the hyperplastic epithelium (composed of epithelium, lamina propria, muscle, and adventitial compartments) becomes an important determinant of airflow limitation. **E** and **F**, When hyperplastic goblet cells release mucins in the airway lumen (pale green circle), swelling of secreted mucins during hydration may result in mucous obstruction. **F**, The contribution of mucous secretions to airflow limitation is increased when smooth muscles shorten. Thus both goblet cell hyperplasia and mucous obstruction in small airways are predicted to contribute significantly to the airflow limitation in chronic inflammatory airway diseases. (Redrawn from Burgel PR, Montani D, Danel C, et al: A morphometric study of mucins and small airway plugging in cystic fibrosis. *Thorax* 62:153, 2007.)

“invaders” (e.g., microbes, inhaled irritants), usually without obvious interference with function. However, in various chronic inflammatory airway diseases, there is evidence of abnormal inflammatory responses, which are involved in the pathophysiologic changes of the diseases. Thus, although secretion of mucus normally plays a protective role in host defense, hypersecretion plays important roles in the pathophysiologic characteristics of various chronic airway diseases. The following section is a brief discussion of some current issues related to mucous hypersecretion in selected obstructive airway diseases. Detailed reviews are provided in the chapters on chronic bronchitis and COPD (see Chapters 43 and 44), asthma (see Chapters 41 and 42), and cystic fibrosis (see Chapter 47).

Figure 10-3 Mucous glycoconjugates and mucins in airway lumens of controls and patients with cystic fibrosis (CF). Representative photomicrographs. Sections containing small airways in a typical control subject (*left panels*) and in a patient with CF (*right panels*) were stained with Alcian blue/periodic acid-Schiff (AB/PAS) for mucous glycoconjugates, blue staining (*upper panels*) or with antibodies to mucin MUC5B (brown staining; *middle panels*) and MUC5AC (brown staining, *lower panels*). In the control subject the airway lumen (L) is empty; no staining for AB/PAS, MUC5B, or MUC5AC is observed in the lumen or in the epithelium. In the patient with CF, the airway lumen is obstructed by a plug containing mucous glycoconjugates (AB/PAS), MUC5B, and MUC5AC only at the periphery of the plug (*arrowheads*), adjacent to the epithelium. Staining for mucins is absent in the center of the plug. Goblet cells in the epithelium are stained positively with AB/PAS and with MUC5AC and MUC5B antibodies (*arrows*). (Original magnification $\times 100$; bar = 100 μm .) (From Burgel PR, Montani D, Danel C, et al: A morphometric study of mucins and small airway plugging in cystic fibrosis. *Thorax* 62:153, 2007.)

BRIEF REVIEW OF CYSTIC FIBROSIS, ASTHMA, AND CHRONIC BRONCHITIS/COPD

Cystic Fibrosis (see Chapter 47)

In CF, mucous plugging has long been known to play a major role in the pathophysiologic changes of the disease, but the extent and characteristics of plugging have previously escaped analysis. Various investigators have reported that mucins contribute to the pathophysiologic changes in CF.^{10,34,35} A biopsy study of conducting airways in CF showed an increase in goblet cell size and an enlarged submucosal gland volume.¹⁷ Kreda and colleagues³⁶ described the relationship between the *cystic fibrosis transmembrane conductance regulator* (CFTR), mucins, and mucous obstruction. In a quantitative analysis of lungs removed at the time of lung transplantation, Burgel and associates¹⁹ reported that in CF most small airways contained extensive plugging,

whereas control lungs contained only rare plugs (*Fig. 10-3*). Another example of plugging in small noncartilaginous airways is shown in *Figure 10-4*. Pulmonary function studies in these CF patients before transplantation were indicative of severe airway obstruction, and the authors suggested that the extensive peripheral airway plugging contributed to the loss of lung function. In the airways with plugs, there was extensive goblet cell hyperplasia, with mucins streaming into the luminal plugs. These studies indicate that CF patients with late-stage disease and severe airway obstruction have extensive peripheral airway plugging, which contributes to the advanced obstruction present and the need for transplantation.

Although mucins play a role in the production of mucous plugs, other components (e.g., neutrophil products), including DNA and extravasated blood products (such as albumin), also contribute. It should be noted that the observation that

Figure 10-4 Mucin plug in terminal bronchiole in a patient with cystic fibrosis (CF). This section was stained with Alcian blue/periodic acid-Schiff (AB/PAS). The plugged bronchiole is surrounded by alveoli.

mucin production is increased in CF does not necessarily imply that CF epithelial cells have increased responsiveness to mucin production, but only that, in the area of plugs, there are stimuli (e.g., *Pseudomonas* bacteria) that effectively stimulate production and secretion of mucins.

In CF, Burgel and associates¹⁹ noted that the staining for mucins occupied approximately 20% of the plugged lumen volume, indicating that mucins contributed to the plugs but that other molecules were also present. Neutrophils were also conspicuous in the plugs. Voynow and coworkers³⁷ reported that elastase, a product secreted by neutrophils, causes the degradation of MUC5AC. Davies and colleagues¹⁸ reported findings that suggested that one airway mucin (MUC5AC) is more vulnerable to proteolytic degradation than the other (MUC5B). The findings reported by Burgel and associates¹⁹ confirmed this observation. The prominent presence of neutrophils in plugged airways suggests the possibility that neutrophil-mediated effects could be involved in proteolytic inactivation of secreted mucins. Many other molecules may also be components of mucous plugs. For example, albumin is a normal component of blood, but, in states of inflammation with increased vascular permeability, albumin is reported to move from the vascular lumen to the airway lumen. Albumin is a plasma protein that can move across the endothelial surface via multiple mechanisms.³⁸ When albumin is present in renal tubular epithelial cells, it activates *epidermal growth factor receptors* (EGFRs) and causes the production of inflammatory mediators.³⁹ If albumin has similar actions in airways, perhaps in diseases with increased vascular permeability, albumin might play a role in activating the EGFR and leading to mucous hypersecretion.

In CF, a disease caused by mutations in the CFTR,^{40,41} exaggerated airway epithelial cell *interleukin-8* (IL-8) production^{42,43} leads to persistent neutrophilic inflammation, a severe and untreated feature of CF airway disease.⁴⁴ Some investigators suggest that inflammatory changes in CF result from infection, and others suggest that the exaggerated effects are intrinsic elements of CF disease. It is known that activation of the EGFR is responsible for the production of IL-8, which is a potent neutrophil chemokine.⁴⁵ Kim and associates⁴⁶ recently hypothesized that normal CFTR sup-

presses EGFR-dependent IL-8 production and that loss of CFTR at the epithelial surface exaggerates IL-8 production via activation of a proinflammatory EGFR cascade. Airway epithelial cells known to contain normal CFTR were treated with a *CFTR-selective inhibitor*, CFTR(inh)-172. The authors found that CFTR(inh)-172 increased IL-8 production via an epithelial surface signaling cascade via the production and release of *interleukin-1- α* (IL-1 α), and binding of IL-1 α to its receptor, leading to EGFR activation and hence exaggerated IL-8 production. (For a description of the cascade leading to exaggerated IL-8 production see Kim.⁴⁶) Similar exaggerated effects were seen in CF epithelial cells. If this cascade is also activated in CF patients in vivo, one would predict that the increased responsiveness of the airway epithelium accounts for the marked increase in the patient's responses. In CF this could explain the effects of *Pseudomonas* infections on the patients' symptoms and their responses to bacterial therapy. These studies are of interest because they suggest that inflammatory responses such as mucous hypersecretion in CF may be due to exaggeration of EGFR proinflammatory responses when CFTR is absent from the epithelial surface. In addition, in other airway diseases, down-regulation of CFTR may also increase EGFR-mediated proinflammatory responses. A limitation of the study is the fact that it was performed in isolated airway epithelial cells. In addition, CFTR(inh)-172 could conceivably have other side effects. Further studies are indicated to determine the validity of the antagonism of CFTR and EGFR and to further investigate the implications. It is possible that understanding the interactions of the CFTR and the EGFR signaling cascades could provide novel therapies.

Asthma (see Chapters 41 and 42)

In contrast to normal individuals, for patients with asthma, sputum secretion and cough, symptoms of hypersecretion in large airways, are common. Thus Turner-Warwick and Openshaw⁴⁷ reported that 77% of asthma patients had a history of sputum production, and 56% reported maximum sputum production at the peak of asthma attacks. Goblet cell numbers in the conducting airways⁴⁸ are increased even in mild asthma.^{11,49}

Chronic asthma has increased as a public health burden over the past 20 years, and acute exacerbations of asthma play important roles in morbidity and cost. Respiratory viruses, mainly rhinoviruses, cause the majority of exacerbations.⁵⁰ Asthma attacks cause the acute onset of symptoms and acute deterioration of lung function. Chronic mucus hypersecretion is a common symptom in adults with stable asthma, particularly in smokers and in patients with severe disease.^{50a} A history of asthma with chronic sputum overproduction is associated with an accelerated decline in maximal expiratory airflow (indicative of airway obstruction).⁵¹ Morgan and colleagues⁵² reported that asthmatic subjects show a greater decline in lung function over time than normal subjects.

Mucous hypersecretion in the large conducting airways causes significant symptoms (cough and mucous hypersecretion).²⁴ Hypersecretion in small airways generally is asymptomatic early but is often ultimately associated with marked airway narrowing (mucous plugging). Further evidence for the involvement of peripheral airways in asthma was provided by Yanai and coworkers,⁵³ who reported that

Figure 10-5 Mucous hypersecretion in fatal asthma. **A**, Alcian blue/periodic acid-Schiff (AB/PAS) staining for mucous glycoconjugates in a proximal airway section in a patient with fatal asthma. The airway lumen is plugged (PLUG) with mucus. The epithelium shows marked goblet cell metaplasia. The submucosal gland (GLAND) has intense staining for mucous glycoconjugates and has released its contents into a gland duct (DUCT) that is filled with AB/PAS-stained material. **B**, Another AB/PAS-stained section of airway epithelium in the same patient at higher magnification. Although goblet cells here remain intact, mucus can be seen streaming from the luminal tips of the goblet cells into the lumen. The lumen is filled with mucus. Both scale bars = 50 μ m.

the majority of the increased airflow resistance in asthmatics resides in small airways.

Widespread mucous hypersecretion was reported in fatal asthma by Cardell and Pearson²¹ in 1959 and was confirmed by other studies.³⁰⁻³³ Mortality in acute asthma is associated with mucous plugging, which is considered to be a major cause of death in asthma. An example of mucous plugging in fatal asthma is shown in Figure 10-5.

In experimental models of allergic airway disease, mucous hypersecretion has also been reported. For example, allergic sensitization by ovalbumin in rats increased mucin production in the airway epithelium,⁵⁴ an effect that was prevented by a selective inhibition of EGFR activation. For details of signaling involved in mucin production, see “[Epithelial Signaling Pathways for Mucin Production](#)” section.

Chronic Bronchitis and COPD (see Chapters 43 and 44)

In the past, mucous hypersecretion was often considered to be an annoying but otherwise benign aspect of airway diseases associated with smoking. Gradually researchers have realized that the clinical implications of the effects of cigarette smoke and other chronic irritants depend on the location and composition of the inhaled irritant. Originally, clinical researchers described a group of patients with symptoms of cough and sputum that were only weakly associated with decline in lung function. The disease was called “chronic bronchitis.” Unlike those in normal healthy persons, submucosal glands located in the large conducting airways of these individuals became enlarged and produced copious secretions, which were cleared in the sputum, assisted by cough.^{55,56} It was reasoned that, if disease in smokers is limited to the large airways and airway obstruction is not prominent, mucous hypersecretion may be disturbing but deterioration of lung function may not become

conspicuous. A correlation was found between the presence of bronchitis and the presence of submucosal gland hypertrophy in the central airways of smokers.⁵⁷ However, it was subsequently shown that chronic mucous hypersecretion is often associated with excessive decline in pulmonary function and increased risk for hospitalization. Mucin production is increased, especially with disease exacerbation and is associated with a decline in forced expiratory volume in 1 second.⁵⁸

Chronic smoking can also lead to progressive obstruction in the small airways, but the changes have been difficult to visualize because of their peripheral location. In addition, the airways are large in number,²⁷ so the majority of small airways must be obstructed before the airflow resistance is increased and causes symptoms. For these reasons, these peripheral airways remain a relatively silent zone until late in the disease. However, morphologic specimens of small airways in COPD, such as in the study of surgical specimens,⁵⁹ showed increased expression of mucins in bronchioles in COPD and an increased number of goblet cells in peripheral airways.⁶⁰ From these results it was concluded that exaggerated mucin production takes place in the bronchioles in COPD.

To examine the role of peripheral airway narrowing, in 1968 Hogg and colleagues⁶¹ showed that the major sites of airway obstruction in COPD are the smaller bronchi and bronchioles less than 2 mm in diameter. In 2004 Hogg and associates²² performed a quantitative assessment of small airways in surgically resected lung tissue in patients with COPD with different degrees of airway obstruction. The progression of COPD was strongly associated with an increase in inflammatory mucous exudates in the lumens of small airways. In addition, they reported an increase in the volume of tissue in the airway wall, which potentiates the

effects of luminal plugging (see Fig. 10-2). These results emphasize the roles of repair processes in the airway wall that decrease the luminal area and thus play important roles in airway obstruction in COPD.⁶²

In a review in 2010 it was concluded that mucus accumulation in conducting airways accounts for the symptoms of patients with COPD.^{63,64} Thus COPD affects central and peripheral airways; effects of the large airways leads to the majority of symptoms, but the peripheral airways appear to be the major sites of airway obstruction. The nature of small airway obstruction in COPD is reviewed by Hogg and colleagues.²² For a more recent review of the roles of small airways in COPD, see Burgel and associates.⁶⁵

EPITHELIAL SIGNALING PATHWAYS FOR MUCIN PRODUCTION

EARLY STUDIES OF MUCINS

Chronic airway diseases have long been associated with mucous hypersecretion. The gel-forming mucins, which are large glycoproteins, became recognized as being responsible for the major characteristics of mucus. Cloning of mucin genes (reviewed by Rose and coworkers⁶⁶) provided tools for studying mucin regulation. In the 1990s, intense research on mucins began, and many stimuli were shown to produce mucins in airway epithelial cells. Based on the newly available cell and molecular tools, rapid advances began to clarify the pathways involved in mucin production. In 1997 Li and associates³⁵ reported that *Pseudomonas* bacteria stimulate epithelial mucin production via a Src-dependent Ras/Raf/MAPK pathway.

EPIDERMAL GROWTH FACTOR RECEPTOR ACTIVATION

Many of the stimuli, such as microbes and cigarette smoke, that induce mucin production in airways are derived from the environment and are inhaled, depositing on the airway epithelial surface. Takeyama and colleagues⁵⁴ hypothesized that receptors on the surface of the airway epithelium could be candidates for epithelial signaling, resulting in mucin production in response to the deposition of the inhaled foreign particulates. EGF, an EGFR ligand, was discovered by Cohen,⁶⁷ and subsequently his group expanded the understanding of EGF and its receptor EGFR, focusing on epithelial cell proliferation and cancer. EGFR is a 170-kd membrane glycoprotein that is activated by multiple ligands.

Takeyama and coworkers hypothesized that epithelial responses to inhaled microbes such as *Pseudomonas* are initiated on the epithelial luminal surface, where the microbes are deposited, by activation of EGFR.⁵⁴ The authors discovered that activation of EGFR by its ligands (such as EGF, transforming growth factor [TGF]- α) cause mucin production in cultured human airway epithelial cells, an effect that is prevented by EGFR inhibition. They confirmed these results in rats in vivo and also found that ovalbumin sensitization increases MUC5AC mucin.

Perrais and associates confirmed that EGFR ligands activate EGFR to produce mucins and reported that downstream pathways include a Ras/Raf/MAPK cascade.⁶⁸ Subsequent reports identified EGFR as a key player in mucin synthesis/goblet cell metaplasia in response to multiple stimuli in vitro and in vivo (see Table 10-1).

METALLOPROTEASES CLEAVE MEMBRANE-BOUND EGFR LIGANDS TO PRODUCE MUCINS

Airway epithelial cells themselves synthesize EGFR ligands in the airway epithelium⁶⁹ as transmembrane precursors that can be cleaved by metalloproteases, releasing soluble active growth factors.⁷⁰ In 1999 Dong and colleagues⁷¹ reported that general metalloprotease inhibitors prevent the effects of EGFR proliferation in proportion to the release of the membrane-bound EGFR ligand TGF- α , and they concluded that the soluble ligand was responsible for the effects of EGFR activation. Prenzel and coworkers⁷² similarly reported that a general metalloprotease inhibitor prevented EGFR ligand release and subsequent EGFR activation. These papers were the first to implicate cleavage of EGFR ligands by metalloprotease(s) in EGFR surface signaling. Subsequently Kohri and colleagues⁷³ linked *Pseudomonas* bacterial supernatant to mucin production. EGFR activation was required, but the mode of EGFR signaling in the airway epithelium was unclear. One clue came from the study of tumor necrosis factor- α -converting enzyme (TACE), a member of the ADAM family of proteases, which is bound to the luminal surface of the airway epithelium. Shao and Nadel⁷⁴ recognized that TACE was capable of cleaving membrane-bound EGFR proligands (e.g., tumor necrosis factor alpha).⁷⁵ Shao and associates⁷⁶ showed that *Pseudomonas* and their product lipopolysaccharide increase mucin production in human airway epithelial cells, an effect that was reported to be EGFR dependent and associated with the cleavage and release of the membrane-bound EGFR ligand, TGF- α . Selective knockdown of TACE prevented the sequence leading to mucin production, establishing TACE as important in autocrine signaling involved in mucin production. These results established the role of TACE in the autocrine activation of EGFR and in mucin production in airways. Subsequently a variety of stimuli have been shown to stimulate mucin production via autocrine EGFR signaling in the airway epithelium.

ROLES OF REACTIVE OXYGEN SPECIES IN AIRWAY EPITHELIAL MUCIN PRODUCTION

Excess production of reactive oxygen species (ROS) is known to cause cell damage in chronic inflammatory diseases.⁷⁷ For example, ROS scavengers inhibit IL-8 production.⁷⁸ Recent studies have contributed to the understanding of the role of ROS in epithelial signaling and mucin production. Thus ROS stimulation (e.g., with H₂O₂) activates EGFR^{79,80} and results in mucin production.¹⁶

Dual oxidase-1 (DUOX1) was found in human airway epithelial cells and was reported to generate ROS.^{81,82} Shao and associates⁷⁴ suggested that DUOX1 could release ROS and thereby activate TACE. They used human neutrophil elastase as the stimulus, because human neutrophil elastase had been previously reported to produce mucin via

Figure 10-6 Diagrammatic scheme of epidermal growth factor-dependent cascade that causes mucin production. Deposition of a stimulus on the airway epithelium activates an epithelial receptor (not shown), stimulating protein kinase C (PKC) isoforms PKC δ/θ , which recruit cytosolic components (e.g., p47phox) to plasma membrane (double-dotted lines) to join dual oxidase-1 (DUOX1) to form an active enzyme system for generating reactive oxygen species (ROS; e.g., H₂O₂; represented by blue dots). ROS activate the latent form of tumor necrosis factor- α -converting enzyme (TACE), which has an inhibitory prodomain (represented by a curved line) covering its catalytic domain (represented by scissors), removing the prodomain and exposing the catalytic domain to cleave pro-transforming growth factor- α (TGF- α ; yellow diamond with a dark tail) into soluble TGF- α (yellow diamond without a tail), which binds to and activates epidermal growth factor receptor, initiating mitogen-activated protein kinase (MAPK) signaling to the nucleus ([N]), leading to mucin gene expression and mucin protein production. (Redrawn from Shao MX, Nadel JA: Dual oxidase 1-dependent MUC5AC mucin expression in cultured human airway epithelial cells. *Proc Natl Acad Sci U S A* 102:767, 2005.)

EGFR ligand-dependent activation.⁸³ Shao and associates⁷⁴ reported that human neutrophil elastase induced TACE activation, TGF- α release, and mucin expression, effects that were inhibited by ROS scavengers, implicating ROS in the response. Knockdown of DUOX1 expression with small interfering RNA prevented the responses. Furthermore, the protein kinase C (PKC)- δ /PKC- θ inhibitor rottlerin prevented the effects of human neutrophil elastase, suggesting that DUOX1 plays a critical role in mucin production via a PKC- δ /PKC- θ -DUOX1-ROS-TACE-proligand-EGFR cascade. The scheme is shown diagrammatically in Figure 10-6. It is of interest that DUOX1 may release ROS in a limited cell compartment adjacent to TACE, thus producing a signal in defense of the host without harmful effects on epithelial cell viability. In fact, DUOX1 is now recognized as playing a role in multiple epithelial defensive responses such as wound healing.⁸⁴ Activation of DUOX1 stimulates the production of the chemokine IL-8.⁸⁵ It is hoped that future studies in various epithelia will evaluate the importance of the proinflammatory cascade in a variety of epithelial-based diseases.

ROS liberated by inflammatory cells recruited to the epithelium may also play roles in mucin production. Neutrophils recruited to the airways and activated are known to produce ROS.^{86,87} When neutrophil supernatant from activated neutrophils was added to human airway epithelial cells, the cells became EGFR phosphorylated and increased mucin synthesis, effects that were shown to be due to EGFR phosphorylation.⁸⁸ However, neutrophils can also produce large amounts of ROS that may cause DNA damage and death of epithelial cells.⁸⁹ Thus, at low concentrations, molecules such as ROS can induce defensive responses such as mucin production, whereas, at higher concentrations, ROS can be destructive. Because ROS appears to play important roles in mucin production, and because studies of ROS-induced modulation are limited, further examination of ROS effects on epithelial cell signaling are in order.

MECHANISMS FOR HYPERSECRETION AND OTHER EXAGGERATED RESPONSES IN OBSTRUCTIVE AIRWAY DISEASES

A major characteristic of chronic obstructive airway diseases is the presence of excess mucous secretion and an increased responsiveness of airway mucous cells to a variety of stimuli. Because these abnormal responses are believed to play major roles in the deterioration and death of these patients, understanding the underlying mechanisms could result in effective therapies. Here we will provide an example of signaling pathways that could produce the exaggerated mucin production in airway diseases. Because exaggerated responses other than mucins also use proinflammatory EGFR cascades, an example involving neutrophil chemokine (IL-8) is included.

On the surface of the airway epithelium, there are two families of receptors of interest: (1) *Toll-like receptors* (TLRs) and (2) *G protein-coupled receptors* (GPCRs) (Fig. 10-7).

TOLL-LIKE RECEPTORS

Multiple stimuli activate airway epithelial cells and produce defensive responses. (For a discussion on innate immune responses see Chapter 12). Because of their importance in studies performed on mucin production, TLRs are included here. Recognition of inhaled stimuli was initiated with studies of inhaled microorganisms. Recognition of pathogens is mediated by a set of germline-encoded receptors called “pattern recognition receptors,” which recognize conserved molecular patterns shared by large groups of microorganisms. An important group of these receptors was discovered in fruit flies (so-called Toll receptors). When

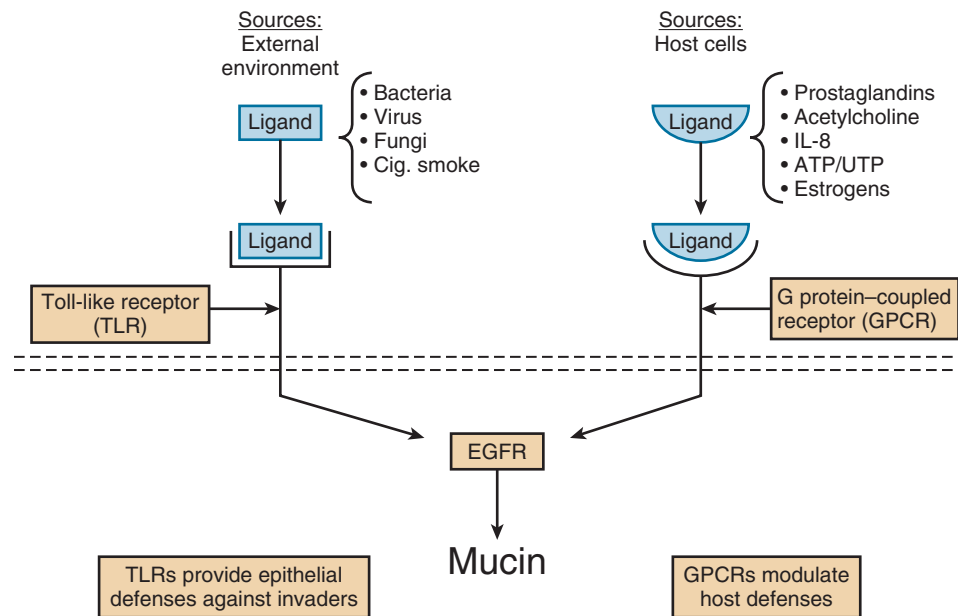

Figure 10-7 Airway epithelial surface signaling cascades activating the epidermal growth factor receptor (EGFR) belong to two major receptor families. (1) Toll-like receptors (TLRs). Inhaled microbes, allergens, and environmental contaminants depositing in the airways signal receptors called TLRs that transmit signals in a cascade to activate EGFRs; this activation, in turn, stimulates downstream pathways that result in defensive responses, including mucin production, interleukin-8 (IL-8) production that causes neutrophilic inflammation, angiogenesis, and production of antibacterial peptides. These receptors relate environmental stimuli to host defensive responses. The signaling may vary over time, and it is likely that the signaling is modified in different disease states. (2) G protein-coupled receptors (GPCRs). This large family of receptors generally modulates epithelial responses from signals generated within the host in the vicinity of the airway epithelium. Stimulation of GPCRs may result in a variety of different cellular responses. ATP, adenosine triphosphate; UTP, uridine triphosphate. (From Nadel JA: Twenty-five years of airway research: personal thoughts. *Proc Am Thor Soc* 7:338–342, 2010.)

they were found in mammals, they were called “Toll-like receptors.”⁹⁰

Early studies of TLRs showed that these receptors are responsible for many of the pathophysiologic effects of microbes. For example, the outer membranes of gram-negative bacteria contain the glycolipid lipopolysaccharide, which is responsible for many of the pathophysiologic features of these bacteria and is due to stimulation of TLR4. Subsequently, many TLRs have been described in mammalian cells, including the airway epithelium. The discovery of TLRs provides a mechanism for microbes to bind to the host epithelium and thus invade. Viral binding to these receptors is important for entry of many viruses into the cell, with consequent viral multiplication. This binding is also an important sensing device, allowing the epithelium to detect the presence of the microbe and then to initiate signaling that provides defensive responses. For example, multiple TLRs are involved in signaling responses to various viruses by IL-8 and by vascular endothelial growth factor production.⁹¹ These results show that multiple TLRs play roles in airway epithelial cell responses by activating EGFR via a complex epithelial cell cascade. Multiple stimuli such as bacterial products,^{76,92} respiratory viruses,¹⁰ and cigarette smoke¹¹ induce mucin production. TLRs receive messages from environmental stimuli (e.g., viruses, bacteria, cigarette smoke) and activate pathways downstream, resulting in EGFR activation and subsequent production of cell products including mucins, and the neutrophil chemoattractant IL-8. Interestingly, the antibacterial peptide cathelicidin LL-37 is also produced by EGFR activation.^{92a} LL-37 also causes activation of EGFR.^{92b} It is likely that selective pathways are produced to modulate these various activities.

G PROTEIN-COUPLED RECEPTORS AND THEIR ROLES IN MODULATING AIRWAY EPITHELIAL MUCINS AND OTHER EPITHELIAL RESPONSES

This family of receptors is very large, constituting almost 1% of the human genome.⁹³ These receptors play a role in regulating cell responses such as in allergic inflammation.⁹³ (For review of G proteins and their receptors see Barnard and colleagues,⁹⁴ Gilman,⁹⁵ and Pierce and associates⁹⁶.) Here we focus on the effects of GPCRs on the exaggeration of airway epithelial mucin responses.

GPCR Can Exaggerate EGFR-Dependent Mucin Production

As described earlier in the chapter, mucins are produced and recruited in the airways as an innate immune response to inhaled “irritants.” In obstructive airway diseases such as COPD,²² fatal asthma,⁹⁷ and CF,¹⁹ exaggerated mucin production leads to mucous plugging.^{9-12,19} Because multiple stimuli cause mucin production in human airway epithelial cells via an EGFR cascade, and because many GPCR ligands induce EGFR activation, Kim and coworkers⁹⁸ hypothesized that EGFR activation could lead to the production of a GPCR ligand, which could induce rephosphorylation of EGFR, leading to exaggerated mucin production in patients with chronic obstructive airway diseases. They used an available, widely used NCI-H292 cancer cell model system for mucin production.⁹⁹ In these cells, but not in the normal epithelial cells, EGFR activation resulted in stimulation of endogenous production and secretion of CCL20 (a GPCR ligand). This resulted in reactivation of EGFR, which led to further mucin production downstream of the second phase

of the EGFR activation. This second phase of EGFR activation was absent in the normal cells. The authors concluded that exaggerated mucin production in the abnormal cells took place via a positive feedback pathway where activation of EGFR leads to the production of CCL20, a GPCR ligand, resulting in EGFR reactivation and exaggerated mucin production. These findings may have potentially important therapeutic implications. Future studies should focus on chronic obstructive lung diseases using epithelial cells from subjects with asthma, COPD, and CF. In vivo studies could help to determine their utility in therapy.

GPCR Can Exaggerate EGFR-Dependent Interleukin-8 Production

In addition to mucins, EGFR activation results in the production of the chemokine IL-8, a potent neutrophil chemoattractant in airway epithelial cells.⁴⁵ In some lung cancers and in chronic obstructive airway diseases, epithelial EGFR activation results in exaggerated production of the neutrophil-recruiting chemokine IL-8.^{100,101} Because both mucin and IL-8 production are exaggerated in some chronic lung diseases and in lung cancer, Kim and associates¹⁰² suggested that GPCRs are involved in the exaggerated IL-8 “proinflammatory” responses. The authors stimulated epithelial (NHBE and NCI-H292) cells directly with an EGFR ligand (TGF- α). In the NCI-H292 cancer cells, EGFR activation led early IL-8 production, followed by the *cyclooxygenase-2* (COX2) dependent *prostaglandin* (PG) E2 production and release. PGE2 stimulated a rephosphorylation of EGFR and resulted in exaggerated IL-8 production by binding to its Gi protein-coupled *E prostanoïd* (EP) 3 receptor. In the normal human epithelial cells, TGF- α -induced EGFR activation did not reactivate EGFR, and less total IL-8 was produced. From these studies we conclude that in hyperresponsive airway epithelial cells, EGFR activation causes a feedback exaggeration of neutrophilic chemoattractant activity via a positive feedback pathway involving COX2/PGE2/EP3 receptor-dependent EGFR phosphorylation.

CFTR MODULATES EGFR-DEPENDENT PROINFLAMMATORY CHEMOKINE PRODUCTION

Mutations in the CFTR protein causes CF, a disease characterized by exaggerated airway epithelial IL-8 production of the neutrophil chemokine IL-8 production, which results in severe neutrophilic inflammation.^{42-44,103} There is growing evidence that the exaggerated IL-8 production is an intrinsic property of airway epithelial cells lacking normal CFTR. Because IL-8 production in airway epithelial cells depends on activation of EGFR,⁴⁵ Kim and coworkers hypothesized that CFTR normally suppresses EGFR-dependent IL-8 production and that the loss of CFTR exaggerates EGFR-dependent IL-8 production via an exaggerated EGFR cascade.⁴⁶ In cultured airway epithelial cells containing CFTR, treatment with the CFTR(inh)-172 induced increased IL-8 production dependent on EGFR, which led to the production and release of IL-1 α . The secreted IL-1 α , bound to its receptor (IL-1R), caused EGFR activation and downstream exaggerated IL-8 production (in excess of constitutive IL-8 production). This study suggests that up-and-

down regulation of CFTR on the epithelial surface may play roles in modulating epithelial inflammatory responses in health and may play important roles in disease. Components of this signaling cascade such as IL-1 α , EGFR, and CFTR may be therapeutic targets for exuberant neutrophilic inflammation in CF and in other inflammatory diseases.

EGFR ACTIVATION DECREASES EPITHELIAL ANTIVIRAL DEFENSES

Because the airway epithelial luminal surface is the first locus of contact of the host and environmental invaders such as respiratory viruses, it is not surprising that the epithelial surface contains an innate antiviral signaling pathway. (For full discussion of innate immunity, see Chapter 12.) *Interferon* (IFN)- λ , a recently discovered type III IFN,^{104,105} has been reported to provide antiviral protection against viral infection.^{105,106} Viruses also stimulate EGFR on the airway epithelial surface, inducing inflammatory responses.^{107,108} Because both of these signaling pathways are initiated at the epithelial luminal surface, it was suggested that this IFN antiviral pathway can be suppressed by viral activation of an EGFR response.¹⁰⁹ The authors report that virus-induced EGFR activation suppresses endogenous airway epithelial antiviral signaling. Influenza virus and *Rhinovirus*-induced EGFR activation suppressed IFN regulatory factor 1-induced IFN- λ production and increased viral infection. Conversely, inhibition of EGFR during viral infection increased IFN regulatory factor 1 and IFN- λ , which resulted in decreased viral titers. Future studies can investigate the EGFR downstream signaling involved. Interestingly, Wark and colleagues¹¹⁰ reported that asthmatic bronchial epithelial cells have a deficient innate immune response, suggesting that there is a link between deficient IFN- β and increased virus replication. These results suggest that epithelial interferons might be therapeutic targets for antiviral therapy.

Future studies are recommended to examine such exaggerated pathways in specific diseases such as asthma, COPD, CF, and cancer.

MUCUS BIOLOGY: PRESENT STATUS AND FUTURE OPPORTUNITIES

The studies of mucus/mucins has resulted in exciting advances, including the importance of the following: (1) the role of airways in the defense against inhaled particulate invaders; (2) epithelial mucins in the clearance of foreign particulates via mucociliary clearance and cough; (3) the physicochemical properties of mucus that lead to effective clearance of invaders; (4) the signaling pathways responsible for efficient clearance of invaders and the abnormal signaling that results in symptoms, deterioration of lung function, and death; and (5) the special and relatively neglected role of mucous obstruction (plugging) of peripheral airways, presently a silent zone in the lungs. We must also encourage further research on the interactions of cells and molecules that lead to disease and the discovery of therapeutics that can alleviate or prevent disease.

Key Points

- Because of their location at the luminal airway surface, the epithelial cells are key components of the host's defensive system.
- Epithelial mucin production and secretion play major roles in clearance of inhaled "invaders" by cough and by mucociliary clearance. Normally mucin production is modest, and inhaled foreign substances are cleared asymptotically and without obvious pathologic changes.
- Multiple stimuli (e.g., viruses, bacteria, cigarette smoke, allergens) induce mucin production by stimulating Toll-like receptors, which recognize the presence of a foreign molecule (e.g., a virus) and respond by activating a signaling pathway that results in mucin production via an *epidermal growth factor receptor* (EGFR) cascade.
- In chronic obstructive airway diseases (e.g., COPD, cystic fibrosis, acute asthma), mucous hypersecretion develops via EGFR-dependent signaling, which causes exaggerated mucin production.
- Mucous hypersecretion in the large conducting airways is manifested in symptoms, predominantly cough and sputum production. Unlike the effects in the large airways, bronchiolar hypersecretion is generally asymptomatic early and consists of luminal mucous plugging, which can ultimately lead to incapacitation and death.
- There is evidence that mucous secretion is EGFR dependent. Recent studies suggest that a special family of receptors, G protein-coupled receptors, could be involved in the exaggerated mucin responses in chronic airway diseases via EGFR positive feedback pathways.
- Recent studies suggest that the proinflammatory effects of EGFR activation are normally antagonized by the presence of the *cystic fibrosis transmembrane conductance regulator* (CFTR) on the epithelial luminal surface. Thus modulation of CFTR could affect EGFR-mediated responses.
- In addition to mucous hypersecretion, chronic airway obstructive diseases also often show other exaggerated inflammatory responses, such as neutrophilic inflammation, which are also EGFR dependent. Analysis of the pathways responsible for the abnormal airway epithelial responses suggests important strategies for therapy of the hypersecretory and proinflammatory effects that are recognized as important in chronic airway diseases.

INTRODUCTION

The human lung has a large surface area, which for an average-size person approximates half a doubles tennis court, thus maximizing the approximation and apposition of capillaries to the epithelial surface. Whereas this design optimizes gas exchange, it also has the intrinsic risk of exposing the delicate alveolar tissues to potentially noxious particles that may be present in the ambient air. There are various safeguards against the danger posed by inhaled particles. The first line of defense is that the configuration of the nasopharynx and serial branching of the airways causes particles to deposit proximal to the more vulnerable alveolar structures.^{1,2} Second, if an insoluble particle deposits in the lung, there are processes by which it can be cleared from the airways or alveoli. Clearance of insoluble particles that deposit in the ciliated airways is achieved by mucociliary clearance.³ The particles are trapped in a mucous blanket, which is then transported proximally by beating cilia. If the cilia are not functioning optimally or if the quantity/quality of the airway mucus is abnormal, the mucus and its entrapped particulates can be cleared by cough. Particles that deposit distal to the ciliated airways are removed by alveolar clearance, mainly by macrophages ingesting the particles and transporting them to regional lymph nodes.

The branching structure of the airways is a barrier not only to noxious environmental aerosols but also to therapeutic aerosols. However, the application of the principles of deposition facilitates the design of therapeutic aerosol development.⁴ For the most part therapeutic aerosols are "targeted" to the lungs, that is, they are designed to treat lung diseases directly and avoid systemic toxicity. Theoretically, the lungs' large surface area can facilitate the sys-

temic delivery of nonrespiratory drugs via the lung as aerosols, usually proteins such as insulin that cannot be given by the oral route. However, to date, the use of this pathway has not had a major impact on clinically successful systemic therapeutic drugs.

DEFINITION AND DESCRIPTION OF AN AEROSOL

An *aerosol* can be defined as a system of solid particles or liquid droplets that can remain dispersed in a gas, usually air. Naturally occurring aerosols, as well as those emitted by clinical aerosol generators, almost always contain a wide range of particle sizes. Because the aerodynamic behavior of an aerosolized particle is critically influenced by its mass, it is important to be able to describe precisely the size distribution of aerosolized particles. In clinical studies the *mass median aerodynamic diameter* (MMAD) and the *geometric standard deviation* (σ_g) are often used to characterize the dimensions of an aerosol. When the mass distribution of particles in an aerosol is fractionated and the cumulative particle distribution plotted as a lognormal distribution on probability paper, it often approximates a straight line. However, recent studies of clinical aerosols have indicated that nebulized particles are often not lognormal in distribution.⁵ The MMAD represents the point in the distribution above which 50% of the mass resides, expressed as the diameter of a unit density (1 g/mL) sphere having the same terminal settling velocity as the aerosol particle in question, regardless of its shape and density.

The lognormal plot is convenient because, if linear, it defines a statistically "normal" distribution and the data

can be described accurately by the MMAD and the standard deviation alone. For a lognormal distribution, one standard deviation is called the “geometric standard deviation,” or σ_g . The σ_g is the ratio of the size at 84% (or 16%) to the MMAD and is an indicator of the variability in particle diameters. If the particle size varies over a wide range ($\sigma_g > 1.2$), it is described as having a *polydisperse* particle distribution; if the particles are of similar size ($\sigma_g < 1.2$), the particle distribution is described as *monodisperse*. Monodisperse aerosols are usually encountered only in research studies where specialized generators are used to create such an aerosol.⁶ For clinical aerosols that are not lognormal and are widely polydisperse, it is best to relate deposition studies to the entire distribution of particles and avoid focusing on simple descriptive terms like the MMAD and σ_g .^{5,7}

The definition of the *mass median diameter* is the same as that of the MMAD except that the data are not normalized to unit density.

PRINCIPLES OF DEPOSITION

The fraction of inhaled particles that deposit (as opposed to being exhaled) is called the “deposition fraction.”^{1,2} The likelihood that a particle will deposit in a particular airway depends on the interaction of three factors: the physical characteristics of the particle (e.g., mass, shape), the gas flow in which the particle is transported (the patient’s breathing pattern⁸ and any velocity provided to the particle by a propellant), and the airway anatomy (especially the presence of airway obstruction⁹). In general, the greater the mass, the faster the velocity, and the narrower the airway, the greater the predisposition of the particle to deposit by a process called “inertial impaction.” Inertial impaction is the dominant mechanism by which particles deposit in the nasopharynx and more proximal airways and describes the process by which a particle fails to follow the air stream in which it is suspended, thereby impacting on an obstacle instead of circumventing it. The probability of a particle undergoing inertial impaction (I) can be estimated using the following equation:

$$I = \alpha(V_t V_a \sin \theta / gR) \quad [1]^1$$

where V_t is the settling velocity of the entrained particle, V_a is the air stream velocity, θ is the angle required to circumvent the obstacle, g is the acceleration due to gravity, and R is the airway radius. The settling velocity (defined in Equation 2) increases as particle size increases. This equation applies to situations in which laminar flow predominates. The presence of turbulent nonlaminar flow will tend to increase impaction further. Particles that fail to deposit in proximal airways by inertial impaction can deposit in peripheral airways and alveoli by a process called “gravitational sedimentation.”

Gravitational sedimentation is the process by which a particle accelerates under gravity until it reaches a terminal settling velocity (V_t), which is determined by the equation¹

$$V_t = (\rho - \sigma)gd^2 / 18\gamma \quad [2]$$

where ρ is the density of the particle, σ is the density of air, g is the acceleration due to gravity, d is the diameter of the

particle, and γ is the viscosity of air. Therefore, for a given velocity, the greater the aerodynamic mass of an aerosol, the shorter the time it will remain suspended in the air stream. Gravitational sedimentation is the main mechanism by which particles (0.5 to 5.0 μm in diameter) deposit in the peripheral regions of the lung.

Sedimentation is critically dependent on the patient’s breathing pattern.⁸ If there is a breath-hold before exhalation, particles are more likely to sediment; without a breath-hold, particles are more likely to be exhaled rather than deposited. It has also been suggested that alveolar volume may affect deposition fraction (larger air spaces require more time for sedimentation).

Very small particles ($<0.2 \mu\text{m}$) can deposit by diffusion. The diffusion coefficient of a particle (D) can be expressed² as

$$D = kT / 3\pi\eta d \quad [3]$$

where k is the Boltzmann constant, T is the temperature in Kelvin, η is the gas viscosity, and d is particle diameter.

These tiny particles are rarely important in therapeutic aerosols, but in inhalation toxicology studies these particles can be produced by combustion and may be clinically relevant, even though they tend to be transient because of the tendency to agglomeration. In addition, man-made nanoparticles, which are of increasing interest in electronics and biomedical research, would, if inadvertently inhaled, be likely to deposit by diffusion (discussed later under “Environmental Aerosols”).

Particles between 0.2 and 0.5 μm in diameter tend to be too small to deposit efficiently by sedimentation and yet too large to deposit efficiently by Brownian diffusion and tend to be exhaled rather than deposited in the lung.^{1,2}

MEASUREMENTS OF PARTICLE SIZE

EVALUATION OF AEROSOL PARTICLE SIZE

Particle size is an important factor in determining whether a particle will undergo nasopharyngeal deposition, airway deposition, or alveolar deposition.¹⁰ Particle size is usually measured by light scattering or cascade impaction: light scattering is based on the principle that there is differential scattering of polarized light by particles of different sizes; cascade impaction is based on a different trajectory of particles of different mass. In cascade impaction, particles at a set flow rate go through a series of apertures of decreasing diameter and impact on a series of plates if they fail to follow the air stream.

Cascade impactors with high flow rates (e.g., 28 L/min) were originally designed for environmental sampling of ambient air to collect 100% of the emitted dose. They have been adopted as the method of choice for monitoring quality control in a manufacturing plant for aerosol delivery. Cascade impaction has an advantage over light scattering in that it facilitates the correlation of different methods of quantifying the distribution of the active drug (e.g., chemical analysis of drug on each plate compared with radioactive label or weight). However, measuring the emitted dose of aerosol using a high-flow cascade impactor is not ideal

for predicting how an aerosol will perform in clinical practice. Although low-flow cascade impactors sample only some of the output, they more closely duplicate *in vivo* conditions.^{5,11,12}

APPLICATION OF IN VITRO MEASUREMENTS OF PARTICLE SIZE TO CLINICAL STUDIES

Particle size measurements using different techniques are not necessarily interchangeable. Meaningful comparisons of the sizes of clinical aerosols, especially those produced by a pressurized *metered-dose inhaler* (MDI; which emits high-velocity particles), can be made only if obtained with identical techniques. Nevertheless, despite the technical difficulties encountered in measuring the size of polydisperse clinical aerosols, some investigators have established that, when used with appropriate caution, data obtained by *in vitro* measurement of particle size do provide useful predictive data for subsequent clinical studies.^{5,7,11}

The classic studies of the influence of particle size on lung deposition were performed with monodisperse aerosols consisting of particles that would not absorb moisture from the air (*nonhygroscopic*).⁶ In contrast, pharmaceutical aerosols tend to be polydisperse liquid droplets, with the active pharmaceutical ingredient (as well as in some cases pharmaceutically inactive excipients such as preservatives and freon) being either in solution or suspended as micronized particles. Droplets can change size by exchanging water with either the dry carrier gas or the humid environment of the upper airway.^{2,13} In addition, some drug ingredients are hygroscopic, and some diluent solutions are hypertonic, both of which could lead to an increase in particle size; the clinical significance of such changes is not known with certainty. It has been reported that hypotonic saline aerosols were associated with a slightly more peripheral deposition pattern on gamma scintigraphy compared with hypertonic saline aerosols.¹⁴ Measuring the particle distribution of droplet aerosols is difficult because the particles can be affected by ambient humidity. Therefore the predictive value of cascade impaction data from droplet aerosols for *in vivo* deposition (e.g., for upper airway deposition as measured by gamma scintigraphy) is strongly dependent on the specific technique used for cascade impaction.¹²

GENERATION OF THERAPEUTIC AEROSOLS

There are three common ways in which therapeutic aerosols can be generated. First, the patient's inspiratory airflow can aerosolize a micronized dry powder (dry powder inhalers). Second, micronized particles can be suspended in a volatile pressurized liquid that vaporizes when at atmospheric pressure, thus imparting velocity to the emitted particles (MDIs). Third, a dispersal force can be applied to a liquid to generate droplets, which are then inhaled by tidal breathing. The generation of the dispersal force can be as simple as using a compressed air source attached to a narrow orifice to generate a Venturi effect (i.e., jet nebulizer) or by more complex vibrating membranes and meshes.

Figure 11-1 Importance of inspiratory impaction using common aerosol delivery systems. Deposition images following inhalation of radio-labeled aerosols: Turbuhaler, a dry powder inhaler (A), and a metered-dose inhaler (MDI), a pressurized chlorofluorocarbon propellant (B). Turbuhaler provided more lung deposition than the MDI. With the MDI, most of the inhaled dose was deposited in the oropharynx and detected in the stomach, after being swallowed (Turbuhaler, 57%; metered-dose inhaler, 81%).

DRY POWDER DEVICES^{4,15,16}

Because dry powder inhaler aerosols are generated by the patient's inspiration, they are by definition coordinated with inspiration (Fig. 11-1A). In optimizing the design of new devices, there is a need to minimize resistance to flow so that weak and tachypneic patients will be able to generate a threshold flow rate. Furthermore, it is desirable that the emitted dose should not vary significantly with changes in inspiratory flow so that intersubject dosing remains consistent. For high-potency drugs, lactose is often used as an inert, bulking agent. Devices can be single-dose devices in which a capsule of powder is perforated in the device (Spiriva HandiHaler, Boehringer Ingelheim, Ridgefield, CT), multidisk with individual doses wrapped in foil blisters¹⁶ (Advair/Seretide Diskus, GlaxoSmithKline, Research Triangle Park, NC), or multidose metered reservoir (Pulmicort Flexhaler, AstraZeneca, Wilmington, DE.). For dry powder devices to maintain reproducible dosing over time, it is critical that the powder be protected from moisture. Despite these technical challenges, the design of dry powder inhalers has greatly improved, and the devices described previously perform at high levels of efficiency and reproducibility.¹⁷

PRESSURIZED METERED-DOSE INHALERS

Pressurized MDIs using chlorofluorocarbon propellants have been used in clinical practice for 50 years and remain the most popular method of administering short-acting rescue inhalers and inhaled corticosteroids. They are portable and discreet. The velocity of the emitted particles, however, requires that for adequate lung deposition, there must be precise coordination with a patient's respiration. Studies have shown that actuation technique is suboptimal in most patients. Even with optimal technique, 80% of the emitted dose may deposit on the pharynx and can cause local irritation (see Fig. 11-1B). In addition, some orally bioavailable medications cause significant systemic exposure from swallowed medication. Valved holding chambers reduce pharyngeal deposition because high-velocity

particles impact on the inside of the chamber and, if the chamber has valves, the need for precise coordination with respiration is obviated.¹⁸ For young children, a face mask can be used in conjunction with a valved holding chamber. Unfortunately, registration studies for MDI medications are almost always performed without a holding chamber because manufacturers do not want their product's prescription tied to a specific holding chamber. To make the chambers more acceptable to patients, effective small-volume chambers (140 mL) and collapsible chambers have been developed.

For the past decade there has been a phase-out program for chlorofluorocarbon-containing pressurized MDIs because of concerns about the impact of chlorofluorocarbons on the environment. Short-acting β -agonists and corticosteroid pressurized MDIs have been reformulated using hydrofluoroalkane as a propellant. The U.S. Food and Drug Administration mandated that these new hydrofluoroalkane-containing pressurized MDIs have performance standards at least equal to existing chlorofluorocarbon-containing pressurized MDIs. Although this task has been far more difficult and expensive than anticipated, the last remaining chlorofluorocarbon-containing pressurized MDIs were removed from the U.S. market in early 2009.¹⁹⁻²¹

JET NEBULIZERS

The ubiquitous small-volume jet nebulizer is the mainstay of bronchodilator delivery in hospitalized patients and patients at the extremes of age. These devices are cheap and require little patient cooperation. In addition, they are useful for delivering medications that have a relatively large mass such as antibiotics. Generation of the driving pressure requires either a tank of pressurized gas or an electric compressor. Although the manufacturers of compressors have made these devices more portable, they are far from convenient for ambulatory patients. In addition, conventional nebulizers tend to take 10 to 20 minutes to deliver a single treatment, which interferes with adherence. Most generic nebulizers are inefficient and deliver less than 10% of the nebulizer charge to the lung. The remainder is left in the nebulizer chamber as so-called dead volume (droplets and dried particles left on the nebulizer walls), lost through the expiratory port because the device generates aerosol throughout the respiratory cycle, or deposited in the extrapulmonary upper airway because most of the emitted dose is contained in large, poorly respirable particles.

NEW DEVELOPMENTS IN AEROSOL DELIVERY SYSTEMS

Manufacturers have made enhancements in nebulizers.²² Internal recycling baffles reduce emitted particle size. Expiratory filters have been added for potentially hazardous aerosols to reduce collateral exposure. Significant enhancements in drug delivery by nebulizers are possible by coordinating nebulization with inspiration (e.g., "breath actuation") that essentially turns the nebulizer off during expiration. Another improvement in efficiency is called "breath enhancement," which uses the patient's inspiratory flow through the nebulizer to increase drug delivery

(e.g., LC Star, Pari, Germany; Ventstream, Medicaid, Bognor Regis, UK).²³

The newer devices include the AKITA (Activaero GmbH, Gemünden, Germany), AER_x (Aradigm, Hayward, CA), eFlow (Pari, Midlothian, VA), and I-neb (Philips/Respironics, Pittsburgh, PA). Each device employs unique proprietary technologies that distinguishes it from the traditional devices. Some tend to be more precise in their coordination with breathing patterns of individual patients (AKITA, I-neb, AER_x); they usually have a lower dead volume in the nebulizer chamber, a greater fraction of particles in the respirable range (i.e., $<5\ \mu\text{m}$), and shorter treatment times.²⁴ They eschew bulky compressors, use either vibrating mesh or crystal, or extrude the liquid through tiny holes or a combination of both vibration and microextrusion.²⁵ They vary in their durability and the relative ease with which they can be cleaned between treatments.

Recently the design of aerosol delivery systems has combined slow and deep inspiration with direct mechanical feedback to the patient for particles of relatively large MMAD. As discussed earlier, a "slow" inspiration reduces particle inertia and allows inhalation of particles that would otherwise deposit in the oropharynx during tidal breathing and will thus minimize oropharyngeal deposition.²⁴

PRINCIPLES OF ASSESSMENT OF DELIVERY SYSTEMS

Assessing effects of an aerosolized drug requires the understanding of three major factors: the characteristics of the aerosol delivery system, the quality of the aerosol produced, and the quantification of deposition within the lungs.^{25a} Quantification of deposition is performed *in vivo* and is time consuming and costly and involves some degree of risk and uncertainty to the patient. The other two components of the aerosol delivery process can be well characterized and studied *in vitro*. The field of aerosol delivery has advanced significantly in the last 10 years so that aerosol delivery characteristics and the quality of the aerosol can be significantly optimized on the bench before exposure to patients.

THE INHALED MASS

Figure 11-2 depicts a simple *in vitro* setup for measuring the quantity of aerosol produced by a nebulizer. A filter that captures the aerosolized particles has replaced the mouthpiece. This system does not require an understanding of nebulizer function from first principles. Because the nebulizer is attached to a breathing device (Harvard pump, Harvard Apparatus, South Natick, MA), the conditions of delivery such as routine tidal breathing can be duplicated. The quantity of drug captured on the inspiratory filter represents the amount that passes the lips of the patient. To distinguish this quantity from a "dose" or deposited drug, the term *inhaled mass* has been coined. The inhaled mass represents "delivery" of drug to the patient constrained by conditions that should mimic actual clinical delivery.

Figure 11-2 Modern testing of aerosol delivery systems can measure inhaled mass and particle distribution for a nebulizer. Breathing patterns are defined by settings on the piston ventilator. Particles presented to the “patient” (the ventilator) are captured on the inhaled mass filter. In separate experiments the cascade impactor measures inspired aerosol. These methods have been useful in simulating patient exposures. (Redrawn from Smaldone GC: Drug delivery via aerosol systems: concept of “aerosol inhaled.” *J Aerosol Med* 4:229–235, 1991, with permission.)

DEPOSITION

The term *deposition* begins to imply a “dose” to the patient. The term *deposition* needs to be further refined in a given situation (e.g., oropharyngeal versus parenchymal deposition, or central versus peripheral deposition within the lung). Each of these terms may be important depending upon the disease entity to be treated. Obviously, the measurement of the actual deposition requires an *in vivo* experiment. However, deposition can be estimated based on parameters that are measured *in vitro* as shown in [Equation 4](#):

$$\text{Deposition} = \text{inhaled aerosol} - \text{exhaled aerosol} \quad [4]$$

Because the term *aerosol* is a little vague with respect to drug activity, [Equation 4](#) can be rewritten as

$$\text{Deposition} = \text{inhaled mass} - \text{exhaled mass} \quad [5]$$

Bench models are useful in identifying the parameters that define the *inhaled mass* for different devices and experimental conditions ([Equation 5](#)).¹¹ Investigators have developed protocols to test the output *in vitro* in ways that more closely replicate clinical practice. For example, bench testing of jet nebulizers can incorporate a piston ventilator to duplicate breathing patterns of spontaneously breathing patients or a ventilator circuit and endotracheal tube to duplicate aerosol delivery in the setting of mechanical ventilation. These *in vitro* protocols can be used to evaluate aerosolization protocols in ways that can optimize pulmonary drug deposition in subsequent clinical studies. For example, in patients undergoing mechanical ventilation, the brand of nebulizer, humidification, ventilator settings, and nebulizer

fill volume are factors that can be optimized *in vitro* before proceeding to clinical studies.^{26,27}

Because pulmonary anatomy is an important determinant of drug deposition, *in vitro* studies are a useful adjunct but not a substitute for clinical deposition studies. Clinical deposition studies are used both to quantify the mass of an inhaled drug deposited in the patient and to determine the regional distribution of drug deposited in the patient.²⁸ Deposition can be divided into extrapulmonary deposition versus pulmonary deposition, whereas pulmonary deposition can be further subdivided into deposition in central airways versus peripheral air spaces. Gamma scintigraphy can be used to acquire both types of data. A radiotracer (usually technetium) is mixed with the study drug and aerosolized and inhaled. The drug deposition images on the gamma camera are superimposed on an outline of the patient’s lung (obtained by a separate radioactive gas study^{29,30} or a transmission image from an external standardized radioactive source³¹). Quantification of lung deposition can be obtained by expressing the radioactivity detected in the lungs as a percentage of the radioactivity initially placed in the nebulizer. One must correct for the attenuation of radioactivity by the patient’s body habitus using the transmission image. It is also necessary to confirm with a cascade impactor that the distribution of radiotracer and drug is identical throughout the range of particle sizes.²⁶ For example, analyzing and correlating both the chemical composition and radioactivity of therapeutic aerosols captured on the stages of a cascade impactor verifies that the distribution radiotracer measured by gamma scintigraphy is a reflection of the distribution of an inhaled gene therapy vector.³²

Figure 11-3 Differences in aerosol deposition between adults and children illustrated by deposition scans from patients with cystic fibrosis breathing the same aerosol. A, A 9-year-old boy with 48% upper airway (stomach) deposition. **B,** A 31-year-old woman demonstrating a more peripheral but patchy distribution but minimal activity in stomach. Aerosols that can readily bypass the upper airways of an adult frequently deposit in the oropharynx of a child. (From Diot P, Palmer LB, Smaldone A, et al: RhDNase I aerosol deposition and related factors in cystic fibrosis. *Am J Respir Crit Care Med* 156:1662–1668, 1997, with permission.)

There are other methods of measuring drug deposition that do not require gamma scintigraphy. A mass balance technique uses filters placed near a patient's mouth to measure the first amount inhaled and the amount exhaled, with the difference being what was deposited in the patient.^{29,30} Pharmacokinetic approaches include comparison of blood levels of aminoglycosides obtained after an intravenous calibration standard to blood levels obtained after inhalation³³ or the urinary concentrations of pentamidine after inhalation.^{34,35} Oral charcoal can be used to block the absorption of swallowed pharyngeal deposited drug so that blood levels will be due entirely to drug absorbed through lung deposition and absorption.¹⁵

STRATEGIES TO OPTIMIZE DEPOSITION OF THERAPEUTIC AEROSOLS

The determinants of aerosol deposition apply to both therapeutic and environmental inhaled particles. To optimize deposition of therapeutic aerosols, a number of strategies have been developed.

GETTING PARTICLES PAST THE OROPHARYNX

In clinical studies, predicting penetration of aerosol beyond the oropharynx and subsequent lung deposition is a major criterion for device selection. Deposition estimations are often based on particle size measurements defined by in vitro characterization of the aerosol produced by a given device. During tidal breathing, most investigators would expect aerosols with particles below 5 μm to be deposited primarily in the lungs (the "fine particle fraction"). Con-

ventional aerosol delivery devices (jet nebulizer, pressurized MDI, and dry powder inhaler) emit particles with a wide range of sizes and velocities. It is estimated that the combined effect of particle size, particle inertia, and the geometry of the oropharynx result in upper airway deposition ranging from 30% to 90% of the total deposition in the patient. Only nebulizers producing particles with particularly small MMAD (e.g., AeroTech II, Biodex, Shirley, NY; MMAD, 1.0 μm) bypass the upper airways (5% oropharyngeal deposition in adults).³⁶ In children the smaller oropharyngeal airways make the task more difficult.³⁷ In children, compared to adults, significantly more drug may be deposited in the oropharynx and less in the lung (Fig. 11-3).

CONTROL OF BREATHING PATTERN AND AEROSOL DEPOSITION

In normal subjects the pattern of breathing is the most important factor affecting aerosol delivery and deposition. How the patient breathes can affect the performance of the device, the particle distribution, the penetration of particles past the oropharynx, and the deposition within the parenchyma. Earlier studies suggested that much of the variation in parenchymal deposition was related to differences in airway geometry between subjects. However, variability in deposition between subjects appears well controlled if the pattern of breathing is controlled. Figure 11-4 depicts data from 11 subjects inhaling 2.6- μm monodisperse particles. The fraction of particles depositing in the lung can be closely related to the period of breathing. In simplified form, points near the origin of the horizontal axis represent normal tidal volumes and frequencies. As tidal volume increases and breathing frequency decreases, the time of inspiration is prolonged (e.g., "slow and deep inspiration"). The curve depicted in Figure 11-4 represents maximum

Figure 11-4 Deposition in the lungs is primarily determined by the pattern of breathing. The data are from 1 subject during controlled breathing (open circles) and from 10 patients during spontaneous breathing (filled circles; data for 2.6- μ m monodisperse particles). The deposition fraction is the fraction of inhaled particles that deposited in the subject. Breathing pattern is defined by a relationship that represents a measure of the period of breathing (tidal volume divided by breathing frequency squared, or V_T/f^2). Typical tidal breathing is found near the origin, slow and deep inspirations appear away from the origin. The deposition fraction varied over a wide range, but changes in the deposition fraction were accounted for by changes in the breathing parameter. (Modified from Bennet WD, Smaldone GC: Human variation in the peripheral airspace deposition of inhaled particles. *J Appl Physiol* 62:1603–1610, 1987, with permission.)

deposition with a slow and deep inspiration for particles of 2.6 μ m. For larger particles the curve would be shifted upward, with deposition approaching 100%.

EXPIRATION AND PROBLEMS WITH AEROSOL DEPOSITION

In normal subjects, those particles that do not deposit during inspiration are largely exhaled completely. Particles that pass through the oropharynx during inspiration enter the central airways and traverse them without difficulty because lobar and segmental bronchi are generally widely patent during inspiration. Then the particles enter alveoli with a few depositing by sedimentation, and, like cigarette smoke, the bulk of the aerosol is exhaled. Deposition is controlled by sedimentation in small airways and is influenced by local geometry and, to a strong degree, by the residence time (period of breathing).

In obstructive lung disease, maximal expiratory flows are diminished. With moderate disease, maximal flows can be superimposed on tidal breathing; as the disease progresses, maximal flows can be reduced even further. Therefore it is common to observe that patients are often breathing on their maximal expiratory flow volume curves even during quiet tidal breathing³⁸ (Fig. 11-5). In these patients, flow-limiting segments exist in the same airways found in normal subjects during forced expiration, but in these patients they form during every tidal breath. Therefore, in patients with obstructive lung disease, deposition in the peripheral lung

Figure 11-5 Tracings of maximal flow and tidal flow versus volume for normal subjects (A) and patients with severe obstructive lung disease (B). Note the difference in size of the axes for the two panels (ordinate: flow range from 0 to 10 or 0 to 5 L/sec; abscissa: volume range from 0 to 2 or 0 to 1 L, respectively). B, For the patients, tidal loops are superimposed on maximal flow volume curves. (Modified from Smaldone GC, Messina M: Flow-limitation, cough and patterns of aerosol deposition in humans. *J Appl Physiol* 59:515–520, 1985, with permission.)

poses a significant challenge because deposition of aerosol is enhanced during expiration at sites of flow limitation (Fig. 11-6). Based on these physiologic considerations, peripheral deposition of aerosol in these subjects would be favored by using a system that combines a slow prolonged inspiration with a breath of sufficiently long duration to promote deposition by settling and to minimize the particles available to the airways during expiration.

For many aerosol applications, inhaling particles “slowly and deeply” solves the problems outlined previously. A slow inhalation will minimize oropharyngeal deposition. “Slow” inspiration reduces particle inertia and allows inhalation of larger particles that would have deposited in the oropharynx during tidal breathing. This concept has been exploited in physiologic studies of mucociliary clearance in the distal airways using particles as large as 6 μ m.³⁹ More recently, commercial applications of these principles have combined slow and deep inspiration with direct mechanical feedback to the patient for particles of relatively large MMAD, resulting in more efficient delivery to the more distal airways (Fig. 11-7).⁴⁰

ADDITIONAL FACTORS INFLUENCING DEVELOPMENT OF THERAPEUTIC AEROSOLS

In addition to efforts to bypass the oropharynx and optimize lung deposition, other factors influence the design of therapeutic aerosols. Some of these factors are disease related and others relate to specific populations.

ASTHMA

One of the most important features of the commercial formulations of inhaled corticosteroids, the mainstay of maintenance therapy for asthma, is reduced oral bioavailability.^{41–43} Many delivery systems for inhaled

Figure 11-6 Particles are deposited preferentially at sites of flow-limiting segments in patients with COPD. Sites of flow-limiting segments (A) and the corresponding deposition image (B) in a patient with severe COPD (posterior view) with a maximal expiratory flow volume curve superimposed on tidal loop (as shown for patients in Figure 11-5B). (Redrawn from Smaldone GC: Advances in aerosols: adult respiratory disease. *J Aerosol Med* 19:36–46, 2006, with permission.)

Figure 11-7 Slow and deep breathing improves aerosol delivery and deposition. Deposition scans from a normal subject after breathing from I-neb, a breath-actuated vibrating nebulizer in which particles are generated only during inspiration: **A**, Following 20 breaths of normal tidal breathing. **B**, Scan repeated after 3 breaths of very slow and deep inspiration (~7 seconds per breath). For slow and deep breathing, deposition was 50 times more efficient per breath, a combination of enhanced delivery and more efficient deposition (unpublished data).

corticosteroids have high levels of oropharyngeal deposition (up to 80% with pressurized MDIs and dry powder inhalers), and it is crucial that, when this oropharyngeal-deposited drug is subsequently swallowed, its systemic exposure be kept as low as possible. The oral bioavailability of beclomethasone as one of the oldest of the inhaled corticosteroids is approximately 20%, fluticasone is approximately 1%, and mometasone less than 1%. A newer drug, ciclesonide, does not become activated until it deposits in lung tissue.⁴³ However, even if there is no oral bioavailability, systemic exposure can still occur when inhaled corticosteroids are absorbed directly into the lung after deposition. It appears that alveolar deposition may give rise to more systemic exposure than airway deposition because particles depositing in the alveoli are not removed by mucociliary clearance and because the alveoli may be more permeable to diffusion than the airway. There are some pharmacodynamic data that suggest that when fluticasone is administered to both normal subjects and asthmatics, the asthmatic subjects are less susceptible to hypothalamic-pituitary-

adrenal axis suppression. This finding is most likely due to the more proximal deposition in the asthmatic subjects because of reduced airway caliber.⁴⁴ Most pharmaceutical manufacturers have therefore tried to target airway deposition while avoiding alveolar deposition. This appears reasonable because asthma is thought to be an airways disease. Some investigators, however, have suggested that there may be an alveolar inflammatory component in asthma, thus suggesting that alveolar deposition may be beneficial.⁴⁵ Nonetheless, this remains a minority viewpoint.

Targeting the airways in asthma is complicated by the polydisperse nature of therapeutic aerosols. Making average aerosol diameter smaller reduces oropharyngeal deposition but increases the amount of alveolar deposition. A low oral bioavailability is more important for polydisperse aerosols with larger MMADs in order to minimize systemic exposure from swallowed drug. Systemic exposure to inhaled corticosteroids can lead to short-term growth suppression in children, decreases in bone mineral density, and possibly an increase in cataracts.^{41–43} Whereas the potential role of

inhaled corticosteroids in prevalence of cataracts is confounded by concomitant use of intermittent systemic corticosteroids, smoking, and ultraviolet light exposure,⁴⁶ an epidemiologic study from Australia that controlled for use of systemic and ocular steroid use found an association between inhaled steroids and the prevalence of cataracts.⁴⁷ Cataracts could be theoretically due to inadvertent spraying of aerosol into the eyes in addition to systemic exposure.

While the search continues for the ideal method of delivery for inhaled steroids to patients with asthma, advances in drug design, formulation, and delivery now provide a wider array of options to the clinician. However, no delivery system can be considered to be intrinsically superior to all others. The delivery system should be judged instead by its ability to optimize the pharmacokinetic properties of the drug, most notably oral bioavailability, and by its suitability for the target subpopulation of asthmatics.⁴

CYSTIC FIBROSIS

Antimicrobials are inhaled for the treatment of cystic fibrosis, for example, tobramycin, aztreonam, and polymyxin. Antibiotics usually require the aerosolization of several hundred milligrams of medication. Jet nebulizers or vibrating mesh devices are usually required to deliver such a large mass of drug. However, only approximately 10% of the dose is deposited in the lungs because of inefficiencies of the delivery systems. Nevertheless, inhalation can be effective at targeting the drug to the lung and avoiding systemic side effects and toxicity. For example, aminoglycosides, when given systemically, have poor airway penetration and are limited by renal and ototoxicity. Inhalation of tobramycin, on the other hand, can result in sputum levels two orders of magnitude higher than those associated with systemic delivery. For the purposes of inhalation, tobramycin was reformulated without the preservative present in the intravenous preparation.⁴⁸ Aztreonam was reformulated with a lysine side chain for inhalation instead of the methionine side chain found in the intravenous formulation, in order to reduce the risk for airway irritation.⁴⁹

For patients with cystic fibrosis, antimicrobials and mucolytics (recombinant DNase) and osmotic hydrating agents (hypertonic saline and mannitol) have been shown to be of benefit.⁵⁰ The multiplicity of inhaled treatments, however, is likely to have a negative impact on patient adherence and therefore creates the need to explore the use of devices with shorter treatment duration in order to improve adherence.

DELIVERY OF INHALED MEDICATIONS TO YOUNG CHILDREN

Asthma is common in children, and delivery of aerosols poses special challenges. There is a need for cooperation and coordination with breathing pattern and a need to generate a threshold inspiratory flow. Thus those younger than 4 years old cannot use a dry powder inhaler. At this age, children may benefit from face masks incorporated with either holding chambers or jet nebulizers. Children between 4 and 6 years of age can use a pressurized MDI, but it should be used with a valved holding chamber because they will have difficulty coordinating actuation with the respiratory

cycle.⁵¹ After age 6 children can be taught how to use a pressurized MDI without a spacer, although the use of spacers should continue to be encouraged.

For young children with asthma, nebulized treatment with a suspension of budesonide is an effective and well-tolerated alternative.⁵² It should be noted that nebulizers tend to be less effective at aerosolizing suspensions than solutions, and clinicians are advised to prescribe budesonide only with the brand of nebulizers used in the clinical trials of this product.

Physicians should be aware that face masks affect MDI-valved holding chambers differently than nebulizers. For masks used with MDI-valved holding chambers, there should be a “tight seal” between the face mask and the face. The lack of a seal will result in marked decreases in effective aerosol delivery, and aerosol experts and package inserts for aerosolized drugs have recommended that aerosol masks should be “sealed tightly to the face.” Recent studies suggest that clinically relevant *in vitro* modeling should include mimicking a child’s breathing pattern and placing the face mask on a model of a child’s face.⁵¹ For a pressurized MDI used with a valved holding chamber, leaks around the face mask have been shown to limit the exchange of tidal air with air in the chamber, thereby reducing the inhalation of aerosol by the patient. For nebulizers, this is not the case. For nebulizers operated with compressors, the face mask can be kept filled with particles in spite of leaks because the compressor flow can exceed the minute ventilation of the child.⁵³ When used with a mask, nebulizers appear to result in less variability in inhaled mass than results with the valved holding chambers.⁵³

It is impossible to seal a mask perfectly to the face. Small leaks, particularly along the nasal-labial fold, create high-velocity jets of aerosol directed to the eyes. Deposition of drugs in the eye may be clinically relevant as shown in Figure 11-8.⁵⁴ Using breathing manikin models and radioactive aerosols, recent experiments have defined the

Figure 11-8 Dilated left pupil in a child following aerosol treatment for asthma. The boy was prescribed both salbutamol and ipratropium bromide inhalers, which were given via a spacer and face mask. This picture demonstrates that aerosolized particles can directly deposit in the eye (see Fig. 11-10). Similar findings have been reported in adults following nebulizer therapy.⁵⁵ (From Brodie T, Adalat S: Unilateral fixed dilated pupil in a well child. *Arch Dis Child* 91:961, 2006, with permission.)

mechanism of this deposition. As shown in [Figure 11-9A](#), nebulized drug can be directed into the eyes using tight-fitting face masks. This effect can be reversed if masks are designed such that linear velocity in the region of the leaks near the bridge of the nose is reduced (see [Figure 11-9B](#)).⁵¹ Although we commonly think that the face mask is a simple

conduit for aerosol particles, human deposition studies in young children have confirmed that face masks commonly cause facial deposition, consistent with the findings outlined earlier using the pediatric manikin. In [Figure 11-10](#), all the commercial face masks were associated with facial deposition.⁵⁶ Even though the incidence of cataract in

Figure 11-9 Serial gamma camera images of a breathing pediatric manikin face following a nebulizer treatment with a face mask. **A**, Facial and eye deposition following nebulizer treatment with a Pari nebulizer and tight-fitting face mask. In this study, more drug deposited on the face than was delivered to the lungs. **B**, Reduced deposition with the same nebulizer and prototype face mask designed to reduce particle acceleration in the region of the eyes. The face mask was modified by opening the area near the nasolabial fold preventing a tight seal and reducing the jet of aerosol directly into the eyes. (Modified from Smaldone GC: Assessing new technologies: patient-device interactions and deposition. *Respir Care* 50:1151–1160, 2005, with permission.)

Figure 11-10 Drug deposition of radiolabeled salbutamol in young children. For all combinations of devices and face masks, the images clearly show facial deposition. This figure illustrates in vivo the important principles demonstrated in the manikin study described in [Figure 11-9](#). Efficient lung delivery requires quiet breathing. Coaching is an important part of nebulized therapy. **A**, Inhaling from a pressurized metered-dose inhaler (MDI)/spacer through a non-tightly fitted face mask. **B**, Inhaling from a nebulizer through a non-tightly fitted face mask. **C**, Inhaling from a pressurized MDI/spacer through a tightly fitted face mask, screaming during inhalation. **D**, Inhaling from a nebulizer through a tightly fitted face mask, screaming during inhalation. **E** and **F**, Inhaling from a pressurized MDI/spacer through a tightly fitted face mask, quietly inhaling. **G** and **H**, Inhaling from a nebulizer through a tightly fitted face mask, quietly inhaling. Deposition on the face is apparent especially for the tight-fitting masks (**C-H**). These principles apply to all patients treated with face masks.⁵⁵ (A-H, Redrawn from Erzinger S, Schuepp KG, Brooks-Wildhaber J, et al: Face masks and aerosol delivery in vivo. *J Aerosol Med* 20[Suppl]:S78–S84, 2007, with permission.)

Figure 11-11 A “blow-by” system can be used for drug delivery with uncooperative children. A ventilated pediatric manikin face is shown during a nebulizer treatment using a face mask. The mask is held away from the face in an attempt to prevent patient withdrawal seen in Video 11-1. Although blow-by is controversial, recent studies have shown that reasonable quantities of aerosol can be delivered (e.g., to the inhaled mass filter) using this technique, provided the proper device-mask combination is used. (From Mansour MM, Smaldone GC: Blow-by as potential therapy for uncooperative children: an in-vitro study. *Respir Care* 57:2004–2011, 2012, with permission).

children receiving inhaled corticosteroids is very low, there is epidemiologic evidence linking inhaled steroid use in adults to an increased risk for cataract.⁴⁷

Finally, children often will not cooperate with face mask therapy. An MDI-valved holding chamber combination will fail to deliver aerosol unless the mask is pressed and sealed to the face. A nebulizer combined with a mask may not be tolerated (Video 11-1). Jet nebulization affords the possibility of “blow-by” therapy, in which the mask is held away from the face and the aerosol directed toward the patient, often in an attempt to minimize patient irritation. Blow-by has been criticized as ineffective,⁵⁷ but recent studies have demonstrated that drug delivery can be maintained using properly tested combinations of nebulizer and face mask⁵⁸ (Fig. 11-11). A newer mask called the “soother mask” incorporates a pacifier in the mask (Video 11-2) that can relax some children.⁵⁹ The points made earlier again reinforce the principle that the physician must work with the patient to decide on the proper device-drug combination when prescribing aerosolized drugs.

DELIVERY OF THERAPEUTIC AEROSOLS TO THE NASAL MUCOSA

Corticosteroids, antihistamines, cromoglycate, and decongestants are inhaled nasally to treat rhinitis. These formulations use large particle sizes to maximize nasal deposition. For children who use inhaled corticosteroids for perennial rhinitis, formulations with low oral bioavailability such as fluticasone, mometasone, and ciclesonide are preferable and reduce the risk for growth suppression.^{60,61}

Among an increasing list of aerosolized medications that are being used to treat diseases of the nasal mucosa are corticosteroids, anticholinergics (ipratropium bromide), saline, and decongestants. Manual pumps that produce large, relatively low velocity particles are being used as an

alternative to high-velocity, freon-based pressurized MDIs. There are isolated reports of nasal perforation with high-velocity inhalers,⁶² and patients should be advised to direct the spray in the direction of the ipsilateral ear and away from the nasal septum. In addition, actuating the inhaler against the lateral wall of the nares reduces the risk for epistaxis (caused by irritating the septum by medial orientation) or headache (caused by stimulating the olfactory nerve by a vertical delivery). In severe allergic sinusitis, the mucosa may be so congested that a short course of systemic corticosteroids may be needed to allow penetration of aerosolized therapy. Prolonged use of topical decongestant sprays may lead to rebound hyperemia and intractable nasal congestion. In certain cases, systemic administration of decongestants may be preferable.

AEROSOL DELIVERY DURING MECHANICAL VENTILATION

Bronchodilators are used to treat patients with airway obstruction while they undergo mechanical ventilation. There is also interest in delivering topical antimicrobial therapy in patients with purulent tracheobronchitis. The dose delivered in this setting can be highly variable, and delivery can be subtherapeutic if certain factors are not optimized. Delivery can be improved by reduced humidification (temporary discontinuation of humidification doubles the delivered dose by reduced rainout of medication), coordination with the respiratory cycle, and the appropriate selection of delivery system. If these factors are considered, delivery can be consistently achieved at doses that approximate those delivered in spontaneously breathing subjects.^{26,27} Using such optimized delivery techniques in critically ill patients with ventilator-associated tracheobronchitis, aerosolized antibiotics decrease ventilator-associated pneumonia and other signs and symptoms of respiratory infection, facilitate weaning, and reduce bacterial resistance and use of systemic antibiotics.⁶³

Delivery of aerosolized β -sympathomimetic agents can also be optimized to a patient undergoing mechanical ventilation. The use of pressurized MDI is feasible provided certain conditions are met.⁶⁴ For example, it is necessary to use a spacer/holding chamber when using a pressurized MDI in this setting. Not all holding chambers are equivalent in efficiency, and different brands are not necessarily interchangeable. In contrast to the treatment of spontaneously breathing patients, delivery during mechanical ventilation must be synchronized with respiration. It is essential that a dose-escalation protocol be employed because doses far in excess of those used for maintenance therapy may be needed. Hence efforts to obtain objective evidence on response to treatment (e.g., peak airway pressure, dynamic compliance) and toxicity (tachycardia, arrhythmias) should be sought. In endeavoring to maximize delivered doses, however, it must be remembered that the efficiency of pressurized MDI delivery decreases significantly if the interval between serial actuations is less than 1 minute and if the synchronization with the respiratory cycle is suboptimal.⁶⁵

In conclusion, once technical factors have been identified and optimized, efficient delivery of aerosolized medications

to patients undergoing mechanical ventilation is readily attainable.²⁷

DIAGNOSTIC RADIOAEROSOLS

In this chapter we primarily discuss the use of radioaerosols as research tools to measure lung deposition and mucociliary clearance. However, radioaerosols are also used in clinical practice.

The radiolabeled ventilation-perfusion scan is an important clinical tool for detection of pulmonary emboli. Perfusion is measured by injecting radiolabeled macroaggregates of protein that impact in capillaries while ventilation is evaluated by a radioactive gas or aerosol. Discrepancies between perfusion abnormalities and ventilation abnormalities are used to assess the probability of pulmonary emboli. The measurement of ventilation should ideally be performed by the use of a radioactive gas (e.g., xenon-133). However, xenon has a relatively long half-life and needs to be trapped after exhalation. In response to these concerns, aerosols labeled with technetium were developed on the assumption that, if ventilation were absent from a lung region, then the aerosol would not deposit in that region. In general, that assumption is true if submicron aerosols are inhaled, but it must be remembered that aerosol behavior is not identical to that of a gas.⁶⁶ For example, patients who are tachypneic with high inspiratory flows and who have airway obstruction will have central “hot spots” (see Fig. 11-6).³⁸ This limits the use of the aerosol techniques in certain patient groups.

MUCOCILIARY CLEARANCE AND DISEASE

Inhaled particles that deposit in the ciliated airways are trapped in a blanket of mucus. This free-floating mucous gel overlies the respiratory epithelium. The equilibrium between the osmotic modulus of the gel and brush layers maintains an adequate periciliary depth to facilitate optimal movement of cilia.⁶⁷ Mucus is transported proximally by the rhythmic beating of these cilia (a fast, forward-power stroke and slower, backward-recovery stroke) to the pharynx, where it is swallowed, a process called “mucociliary clearance.”³

Ciliated respiratory epithelial cells are most numerous in the tracheal and lobar bronchi and decrease progressively in more distal airways. Secretory cells are also more numerous in proximal airways: goblet cells produce thick carbohydrate-rich secretions, whereas other cells produce more serous secretions. In diseases such as chronic bronchitis and bronchiectasis, the number of goblet cells increases in more distal airways. Airway secretions are also produced by submucosal glands. The latter are lined by mucinous and serous epithelial cells and become hypertrophic and hyperplastic in chronic bronchitis and other types of chronic airway inflammation.

Mucociliary clearance can be impaired by intrinsic defects in ciliary function, which can be congenital (primary ciliary

dyskinesias) or acquired (tobacco smoking, influenza). Mucociliary clearance impairment can also be due to changes in the quantity and composition of airway secretions (chronic bronchitis, cystic fibrosis). Adequate hydration of airway secretions is essential for optimal mucociliary clearance.⁶⁷ Chloride and sodium channels in the airway epithelium have key roles in regulating the water content of airway secretions.^{68,69}

If the mucociliary apparatus is significantly impaired, secretions are cleared predominantly by coughing. If both mucociliary clearance and cough clearance become ineffective, retained secretions produce both physical obstruction of the airway lumen and amplification of the underlying inflammatory processes.

Mucociliary clearance in healthy subjects is usually completed within 24 hours of deposition.³ The mucous path can be followed using radiolabeled aerosols (Video 11-3). Particles containing technetium-99m and bound to a molecule that prevents absorption into the circulation can deposit on ciliated airways and follow the clearing mucus. Particles deposit in proximal airways by inspiratory impaction (larynx, mainstem, lobar, and segmental bronchi). Extrapulmonary deposited particles will be swallowed and appear in the gamma scintigraphy as stomach “hot spots” overlying the left lower lung field.

Primary ciliary dyskinesia is a congenital disorder of the dynein arms of the cilia.^{3,69a} The normal cilium has nine pairs of dynein peripheral arms and two central pairs. Each pair consists of an inner and outer dynein arm. A variety of genetic abnormalities can result in loss of the ciliary movement. In the absence of the ciliary movement, these patients will have mucous stasis and develop bronchiectasis and sinusitis. In males, ciliary dyskinesia is also associated with infertility due to immotile spermatozoa. There are associated abnormalities of visceral organs, such as situs inversus and dextrocardia.⁶⁷

Cystic fibrosis, the most common fatal single-gene genetic disease in Europe and North America, is associated with severe bronchiectasis.^{3,69b} The mucus becomes dehydrated and less easy to clear because of an impaired chloride channel (*cystic fibrosis transmembrane conductance regulator* [CFTR]) which leads to reduced secretion of chloride into the airway lumen.⁶⁸ In addition, an increase in epithelial sodium channel activation due to inflammatory proteases promotes absorption of sodium from the lumen, further exacerbating the dehydration of mucus. Hypertonic saline, when administered to the airways of patients with cystic fibrosis, creates an osmotic gradient that draws water into the airway lumen, and this treatment is associated with decreased rates of acute exacerbation.⁷⁰ Inhaled mannitol is an alternative inhaled osmolyte for patients with cystic fibrosis that has been approved by some regulatory authorities.⁷¹ In patients with a rare mutation of the CFTR gene (G551D), ivacaftor, a novel agent administered orally, can potentiate the opening of the CFTR channel.⁶⁹ The clinical benefits associated with ivacaftor therapy, including improving lung function and decreasing rates of acute exacerbation, would appear to validate the concept of the need to optimize airway hydration. Trials are underway to determine if the more common genotypes of cystic fibrosis would benefit from potentiator therapy. In addition, there is

interest in studying if blocking epithelial sodium channels in the presence of hypertonic saline could also increase the water content of mucus. Inhaled amiloride can block epithelial sodium channels, but its brief half-life at the airway epithelium limits its clinical effectiveness.^{69,72} The airway secretions in cystic fibrosis not only contain mucus secreted by the airway but also consist of DNA and actin from dead neutrophils. Recombinant DNase, administered by inhalation, can facilitate clearance of secretions and destroy neutrophil extracellular traps, the extracellular DNA released by neutrophils at sites of infection.

In chronic bronchitis there is hypertrophy and hyperplasia of the submucosal glands, as well as an increase in the number of goblet cells and the presence of goblet cells in more distal airways compared to normal. The resultant mucus has an increase in the mucous component relative to the serous component, which means that the mucous layer is relatively dehydrated.^{68,73}

In patients who die of status asthmaticus, the airways at autopsy are filled with inspissated mucus. The mucus in patients with status asthmaticus has abnormal viscoelastic static properties that may be due in part to excessive cross-linking of mucous glycoproteins.⁷⁴ Clearance of radiolabeled mucus is severely impaired in patients with status asthmaticus, but mucociliary clearance can recover within weeks.⁷⁵

Impairment of radiolabeled mucociliary clearance may be an index of disease severity in asthma,^{75,76} COPD,⁷⁷ and cystic fibrosis.⁷⁸ Serial measurements of mucociliary clearance can be useful in measuring pharmaceutical enhancement of mucociliary clearance, as for example, in the sustained effects of hypertonic saline in cystic fibrosis.

In conclusion, mucociliary clearance is impaired in asthma, chronic bronchitis/COPD, cystic fibrosis, bronchiectasis, and primary ciliary dyskinesia. Cough clearance augmented by physical therapy and other mechanical interventions (flutter valves, vibration vests) provides some treatment, but pharmaceutical interventions are limited.

ALVEOLAR CLEARANCE

Particle solubility affects clearance in alveoli. Soluble particulates may be absorbed through the thin membrane of the peripheral air spaces.^{3,79,80} Insoluble particulates, however, tend to be phagocytosed by alveolar macrophages. Their metal content influences the free radical generating properties of the particle and can promote inflammation, especially when the particle is delivered to the lysosomes. Lysosomes have a very low pH designed to kill microorganisms, but the low pH may promote solubility of transition metals such as ferrous iron and therefore be proinflammatory.

Responses to preexisting inflammation may be important because cells that are primed by one type of inflammation (e.g., by tobacco smoke or endotoxin) may be more reactive to a second stimulus from an inhaled particulate. Inhaled dose is important, and excessive exposure can lead to overloading of alveolar macrophages, which can be proinflammatory even with relatively nonreactive particulates.⁸⁰

Macrophages migrate to regional lymph nodes, and some particles are characterized by a distinctive adenopathy (e.g., silicosis and its eggshell calcifications).

ENVIRONMENTAL AEROSOLS

TOXINS

An appreciation of the principles of aerosol deposition and clearance is essential both in understanding the epidemiology of illness from exposure to environmental aerosols and in developing rational strategies to reduce the impact of those exposures. The impact of exposure to an aerosol depends on a number of factors, some of which are self-evident and others that are less apparent. These factors include the total mass of particulates in the air, the size distribution, the shape and surface area of particles, the chemical composition of the particles, the level of ambient turbulence, the airway anatomy and breathing patterns of exposed individuals, and the immune response to inflammatory or infectious agents.^{80,81} Exposure of rodents to high doses of low-toxicity, poorly soluble particulates results in pulmonary inflammation,⁸¹ impairment of alveolar clearance,⁸² and an increased tendency to develop tumors.⁸¹ It is, however, not yet clear if it is appropriate to extrapolate from studies using high-dose exposures in rodents to determine rational exposure thresholds for humans.⁸¹ Unfortunately, it appears that in vitro exposure of cell cultures to environmental particulates correlates poorly with in vivo animal exposures.^{83,84}

In December of 1952 in London, England, 4000 excess deaths were attributed to smog. This disaster had a huge impact on public health policy and led to efforts to reduce the impact of air pollution. At the time, it was assumed that it was the total concentration of particulates that was the most important determinant of mortality. However, retrospective analysis of stored autopsy specimens suggested that exposure to fine particulates and metals may have been more important than the total mass of exposure.⁸⁵ The increased emphasis on particle size was supported by a series of urban epidemiologic studies that found correlations between daily concentrations of particulates and mortality. Using data from urban sampling devices that can measure the amount of particles less than 10 μm in diameter, it was demonstrated that even small increases in particles less than 10 μm in diameter produced an increase in acute death rates.⁸⁶ Interestingly, it was cardiovascular deaths that seemed to dominate over respiratory deaths, leading to speculation that the deposition of particles in the lung could activate proinflammatory cascades. Later studies, using even more sophisticated samplers, found a correlation between mortality and fluctuations in the fine particles less than 2.5 μm in diameter.⁸⁷ More recent research has focused on even smaller particles between 1 and 100 nm.⁸⁸ When these are found in the atmosphere, usually as result of combustion, they are referred to as “ultrafine” particles; when they are manufactured in the semiconductor, pharmaceutical, or chemical industries, even though their dimensions are also 1 to 100 nm, they are referred to as “nanoparticles.” In contrast to ambient ultrafine particles, which tend to be polydisperse,

nanoparticles are more monodisperse. Measuring particle size distributions in the nano spectrum requires more sophisticated techniques than for conventional particles. Spectrophotometry, atomic force microscopy, and complex light scattering techniques have been developed to make these measurements. As particles approach the nano range, their behavior can change. Both ultrafine and nanoparticles can deposit by diffusion, have a very high deposition fraction, and are small enough to pass between epithelial cells in the lung and cause systemic toxicity. Surface area of the inhaled particles may become more important than total inhaled mass in understanding their toxicity. For example, titanium is a relatively inert and nontoxic substance when inhaled as a typical respirable aerosol (0.5 to 5 μm particle size), but exposure to titanium particles within the nano range results in marked cytotoxicity and proinflammatory effects in the lungs of rats. These effects have led to calls for tighter regulation of nanoparticle manufacture and distribution of nanomaterials.

Application of the principles of aerosol deposition can reduce exposure to toxic environmental aerosols. For example, dust mite fecal aerosols tend to be large and have a relatively rapid settling velocity.⁸⁹ However, the energy imparted by a ceiling fan can prolong their residence time and facilitate their inhalation; hence asthmatic patients are advised to eschew the use of ceiling fans in their bedrooms. Most naturally occurring aerosols have sufficiently large particles to be filtered by the nose and the branching structure of the large central airways. Some aerosols, however, pose particular dangers. Asbestos fibers, despite being relatively large, can deposit in small peripheral air spaces because their cylindrical structure allows them to follow the air stream to the lung periphery.⁹⁰ As discussed previously, ultrafine aerosols pose an additional danger if inhaled. They can pass between the protective epithelial cells of the lung and cause systemic toxicity. Deposition of environmental aerosols is affected by particle size and shape and also by breathing pattern. Generation of aerosols by workers who are performing manual labor and have increased inspiratory flow rates and minute ventilation can result in an increased dose deposited in the lung. Although larger particles have low peripheral deposition, these particles can nevertheless be hazardous because of their mass. For example, after the attack on the World Trade Center, particles greater than 50 μm were deposited in peripheral air spaces because they were present in very high concentrations in the air for hours after the collapse of the towers. Consequently, New York City firefighters who responded to the disaster site on the day the towers collapsed had significantly higher rates of lung injury than those who reported on day 2.⁹¹ The toxicity of inhaled inorganic particles is complex and beyond the scope of this text. Factors influencing toxicity include the metal content of particles, especially transitional metals such as iron, which may influence free radical generation.⁹²

Tobacco smoke remains one of the most important indoor exposures to toxic aerosols. Some of the principles of aerosol delivery and deposition are useful in explaining some of the epidemiologic associations with different types of cigarettes.^{89,93} Despite marked differences in “smoking-machine”-generated concentrations of tar, cigarettes marked as medium tar, low tar (“lite”), and ultralow tar

(“ultralite”) are associated with similar incidences of lung cancer. (High-tar unfiltered cigarettes are associated with an even higher incidence of lung cancer.) The explanation for this paradox appears to lie in part with the fact that a standardized smoke generator does not reproduce the actual smoker’s exposure. For one thing, ventilation holes in the “lite” cigarettes that dilute the machine-generated smoke can be occluded by human lips, thereby increasing the exposure to smoke from the “lite” cigarettes. However, a more important factor may be that people tend to inhale the smoke of the “lite” cigarettes more deeply and deposit carcinogenic particulates in the more distal air spaces. This latter theory is supported by the observation of a relative increase in the incidence of more peripheral adenocarcinomas relative to more central squamous carcinomas following the introduction of “lite/ultralite” cigarettes to the U.S. market, where they now hold an 80% market share.⁹³

INFECTIOUS AEROSOLS

Toxic aerosol exposures, although complex and multifactorial, can usually be reduced by avoidance. Infectious aerosols raise additional problems because simple avoidance is not always possible. For example, the health care worker must provide care, and it is often not possible to define minimal safe exposures.

Pulmonary tuberculosis is an infection spread exclusively through the inhalation of infected droplet nuclei (1 to 5 μm), nuclei that form after the evaporation of expectorated droplets and that can remain airborne for hours in ambient air.⁹⁴ Influenza can be spread by direct contact and by large (>10 μm) and small (<5 μm) droplets. Prevention of spread of airborne infections is a growing health care problem in hospitals and in the community. Current practice includes placement of a face mask on patients with suspected tuberculosis or communicable respiratory viral infections to intercept cough-generated aerosols before they have the opportunity to dry and become airborne, where they can float for many hours. In hospitals, current practice also includes use of tight-fitting masks on the health care worker so that all their inspired air is filtered by the mask with the thought that the aerosols are small enough to follow the air stream and pass around loosely fitting masks. However, the efficacy of this technique is unknown. The Centers for Disease Control and Prevention recommends surgical masks for seasonal influenza but recommended N95 respirators for the 2009 pandemic H1N1 virus.⁹⁵⁻⁹⁸ The former recommendation is based on the assumption that transmission of seasonal influenza is via direct contact or by inhalation of large, airborne droplets⁹⁹ (>5 μm); the latter recommendation for the more dangerous H1N1 virus is based on the assumption that all particles, including aerosolized particles (<5 μm), would be better intercepted by the greater filtration capability of N95 respirators.¹⁰⁰ However, there is no firm understanding of the various potential transmission mechanisms for influenza.^{96,97}

In vitro studies designed to assess mask efficacy have focused on filtration masks as the only mechanism of protection.¹⁰¹ More recently, interactive models of aerosol exchange in defined environments have suggested that simple filtration of particles is often not the primary mechanism of protection (Fig. 11-12). Transmission of infectious

Figure 11-12 Transfer of infectious aerosols from an infected individual (Source) to an uninfected health care worker (Receiver). Infectious particles may be affected by the breathing pattern, dilution by ambient air, extraction via air flow (e.g., a negative-pressure room in a hospital), filtration by either mask, or deflection by mask. Most studies defining hospital policy and health care worker protection have focused on filtration only. (Redrawn from Diaz KT, Smaldone GC: Quantifying exposure risk: surgical masks and respirators. *Am J Infect Control* 38[7]:501–508, 2010, with permission.)

Figure 11-13 Testing chamber to evaluate the transfer of infectious aerosols depicted in Figure 11-12. The Source and Receiver are represented by ventilated manikin heads, air flow in the room mimicked a hospital negative-pressure room (e.g., air flowing in under the door and out a vent behind the patient), and radiolabeled test aerosols were generated via a nebulizer, exhaled by the Source, and inhaled by the Receiver. Receiver exposure was quantified by a filter in the Receiver, and aerosol distributions were measured by cascade impactors placed in different locations in the chamber. (Redrawn from Diaz KT, Smaldone GC: Quantifying exposure risk: surgical masks and respirators. *Am J Infect Control* 38[7]:501–508, 2010, with permission.)

aerosols between human subjects is more complex, involving multiple mechanisms of aerosol transport, and thus suggests potentially unexpected solutions. For example, which is better, putting the protective mask on the infected individual or on the uninfected health care worker? These questions are very difficult to answer in clinical situations. Recent *in vitro* studies based on the concepts illustrated in Figure 11-12 have suggested that putting a simple surgical mask on the infected source (respiratory source control) is far more effective than trying to filter out all the particles inhaled by an uninfected health care worker.¹⁰² For example,

when the behavior of exhaled and subsequently inhaled aerosols between individuals was tested in a controlled chamber designed to mimic a negative-pressure room in a hospital (Fig. 11-13), far better protection of the health care worker was achieved when an inexpensive surgical mask was placed on the source compared to all forms of masks placed on the health care worker, including one sealed directly to the face with petroleum jelly (Fig. 11-14).¹⁰² Additional epidemiologic studies are needed to design the best protection from ambient infections in the community and in health care facilities.

Source		Receiver		Workplace Protection Factor
—			—	1
Tight Surgical Mask			—	288
—			Tight Surgical Mask	2
—			N95	1
—			N95 + Petroleum Jelly Sealant	118

Figure 11-14 Data from test chamber described in Figure 11-13. Receiver exposure was quantified by a so-called simulated workplace protection factor, the ratio of exposure without face mask protection divided by exposure with face mask protection (higher numbers are better). Placing a mask on the source was far more effective than masks on the receiver. N95, an N95 respirator; N95 + petroleum jelly sealant, an N95 respirator sealed to the manikin by petroleum jelly to prevent any leaks; Tight Surgical Mask, a surgical mask tied tightly around the face. (Modified from Diaz KT, Smaldone GC: Quantifying exposure risk: surgical masks and respirators. *Am J Infect Control* 38(7):501–508, 2010, with permission.)

In conclusion, further progress in understanding of the role of environmental aerosols in health and disease will be dependent on the collaboration of several disciplines. An appreciation of the principles of deposition and clearance by the participating investigators should facilitate interdisciplinary communication and cooperation.

Key Points

- The likelihood that a particle will deposit in an airway depends on the physical characteristics of the particle, the gas flow transporting the particle, and the airway anatomy. The greater the mass, the faster the flow, and the more narrow the airway, the greater is the potential for inertial impaction. For the clinician, forces that define inertial impaction are most important in determining upper airway deposition and the passage of aerosol into the lungs.
- Once particles pass through the upper airways, deposition in the lungs is largely defined by sedimentation.

This process is dependent on a subject's breathing pattern, both the depth and the duration of the breath.

- Holding chambers reduce pharyngeal deposition and reduce the need for precise coordination to get the full dose.
- Face mask seal and design can be an important factors in the delivery of clinical aerosols.
- Compared to parenteral therapy, medicines can be delivered by aerosol in greater concentration to the target organ, the lung, with fewer side effects, but most traditional jet nebulizers are inefficient and deliver less than 10% of the drugs to the lung.
- Directing the jet of high-velocity nasal sprays laterally avoids the side effects of headache when directed vertically and epistaxis when directed medially.
- Mucociliary disorders, which can be inherited or acquired, can result from changes to the structure of the cilia or from changes in the composition or quantity of the mucus.
- Environmental aerosols, especially the fine particulates, result in excess acute deaths, often from cardiovascular events.
- Prevention of spread of infectious aerosols can be enhanced by placing a simple face mask on the patient, a strategy called “respiratory source control.”

OVERVIEW OF THE COMPONENTS OF LUNG INNATE IMMUNITY

INNATE RECOGNITION IN THE LUNG

Secreted Pattern Recognition Receptors

Cellular Pattern Recognition Receptors

Summary

EFFECTOR MECHANISMS

Epithelium

Polymorphonuclear Leukocytes

Mononuclear Phagocytes

SYSTEM INTEGRATION

INTRODUCTION

The immune system is broadly conceptualized as having two separate but interconnected arms. In evolutionary terms the *innate immune* arm is an older and more primitive system that has developed to provide early host defense against viruses, fungi, and bacteria. The fundamental basis of innate immunity is a system for pathogen detection that relies on the recognition of a range of *pathogen-associated molecular patterns* (PAMPs), which include complex lipids, carbohydrates, unmethylated cytosine-guanosine DNA sequences, and double-stranded RNAs. PAMPs are recognized by a series of secreted, cell surface, and intracellular *pattern recognition receptors* (PRRs) that promote the recognition, phagocytosis, and killing of many microbes. In addition, recognition of PAMPs by PRRs initiates inflammation, which in turn leads to the recruitment of phagocytes that kill and degrade microbes, promote the repair of damaged tissues, and assist in the restoration of tissue function. Though some organisms, for example, sea urchins, have evolved a system of host defense based exclusively on the innate immune system,¹ mammals and higher animals have evolved an *adaptive immune system* that differs from the innate immune system in its exquisite antigenic specificity and the ability to develop immunologic memory, allowing a more rapid response to previously encountered microbes and antigens. Both the innate and adaptive immune systems operate together and exist in a classic symbiotic relationship to provide optimal defense of the lung and other organs and tissues (see Chapter 13).

The broad concepts of innate and adaptive immunity outlined previously have evolved to protect most organs and tissues from *microbes*, a term we use to include bacteria, yeasts, fungi, protozoa, multicellular parasites, and viruses. However, most organs and tissues, including the lung, have evolved additional mechanisms to tailor the immune system to their own specific needs. The lung epithelium has a surface area approximately the size of a tennis court and represents the largest epithelial surface in the body. With an average respiratory rate of 10–12 breaths/min and an average tidal volume of 600 mL, the lungs are exposed to over 10,000 L of ambient air per day. The air that we breathe is a complex mixture of gases and particulates that can contain pollutants, oxidants, inorganic and organic dusts, pollens, toxins, bacteria and their constituents (e.g., bacterial endotoxin, *lipopolysaccharides* [LPSS]), and viruses.

In addition, the airways and gas-exchange surfaces of the lung can be exposed by aspiration to acidic gastric contents as well as to infected mucus from the nasal sinuses. Thus all surfaces of the respiratory tract from the nasal passages to the alveoli are constantly exposed to a spectrum of harmless, harmful, and pathogenic agents, raising the key question of how the lung differentiates between what is harmful and what is essentially harmless.

Like the gut, the lung has evolved discriminative mechanisms both to suppress unwanted and potentially harmful responses to harmless materials and to retain the ability to activate a vigorous innate and adaptive immunity when encountering harmful microbes and stressors. The overall goal of this chapter is to review current concepts of lung innate immunity and its fundamental underlying mechanisms. Multiple cell lineages participate in innate protection of the lung, and many share similarities in the way they recognize and respond to microbes and other harmful agents. Therefore we have organized the chapter into four broad sections. First, we provide an overview of lung innate immunity and its fundamental components. Second, we discuss general mechanisms of innate immune recognition. Third, we review innate lung cells and the effector mechanisms they use. Fourth, we discuss how these systems and mechanisms are integrated. Throughout the chapter we also discuss how the innate immune system primes the adaptive immune system as a prelude to the chapter on adaptive immunity (see Chapter 13).

OVERVIEW OF THE COMPONENTS OF LUNG INNATE IMMUNITY

Microbial species can rarely be cultured from the lungs of healthy individuals, leading to the long-standing dogma that the lower airways and gas exchange surfaces of the lungs of healthy subjects are sterile. However, recent studies based on culture-independent methodologies, especially bacterial 16S ribosomal RNA sequencing, have begun to challenge this notion. Based on an earlier single-center study with a modest number of subjects,² a recent National Heart, Lung, and Blood Institute–sponsored multicenter study with 64 subjects has provided data to indicate that bacterial DNA is present in the bronchoalveolar lavage of healthy subjects and that most sequences resemble the

Figure 12-1 Overview of innate immune protection in the conducting airways (upper) and alveoli (lower) of the lung. **A**, In the absence of pathogen-associated molecular patterns (PAMPs), that is, in the steady state, the airways are protected by mucus that captures harmless particulates and transports them along the mucociliary escalator. Dendritic cells (DCs) also capture particles, traffic to regional lymph nodes, and promote tolerance to commonly inhaled antigens. Also in the absence of PAMPs, the alveoli are maintained in an anti-inflammatory and immunosuppressed state to prevent unwanted inflammation and immune activation toward commonly inhaled particles and antigens. **B**, In the presence of PAMPs, innate immunity is activated. PAMPs stimulate airway epithelial cells to express chemokines, cytokines, and lipid mediators that attract neutrophils (polymorphonuclear leukocytes [PMNs]), which in turn kill PAMP-expressing microbes. Airway dendritic cells respond to PAMPs by maturing, migrating to regional lymph nodes, and stimulating T-cell proliferation. A similar program is activated in the alveoli upon PAMP detection by alveolar macrophages, alveolar epithelial cells, and dendritic cells, resulting in the initiation of inflammation and activation of adaptive immunity. SP-D, surfactant protein D.

diversity seen in the mouth. However, sequences from Enterobacteriaceae, *Haemophilus*, *Methylobacterium*, and *Ralstonia* species were disproportionately represented in the lung.³ Although it is unclear if these lung enriched sequences are derived from bacterial communities colonizing the throat, nasal passages, or gastrointestinal tract (which were not sampled for comparison) or whether or not they were derived from viable bacteria, these findings provide hints that commensal bacterial communities may exist in the lungs of healthy individuals. Thus, it will become increasingly important to integrate emerging information on lung microbiota into our understanding of how the innate immune system interfaces with these potentially commensal bacteria.

Given this caveat, the innate immune system is currently conceptualized as providing protection to the lungs against a diverse spectrum of inhaled particles and antigens that range from harmless nonmicrobial particles (e.g., dusts and pollens) to harmful pathogenic microbes (e.g., *Mycobacterium tuberculosis*). To accomplish the range of protection, the lungs have evolved multiple mechanisms to survey and respond to inhaled particles based primarily on their size

and physicochemical properties, especially the presence and absence of PAMPs. As illustrated in Figure 12-1, innate immune protection in the lung can be broadly divided into considerations of the conducting airways and the gas-exchange surfaces of the alveoli. At the cellular level, innate protection is afforded by the coordinated functions of airway and alveolar epithelial cells, resident macrophages and dendritic cells (DCs), and recruited neutrophils (polymorphonuclear leukocytes [PMNs]), monocytes, and DC precursors.

Though often underestimated, an important component of airway host defense resides in the anatomic structure and epithelial cell lineages of the tracheobronchial tree. Air turbulence created by the nasal passages and the cartilaginous segmentation of the trachea and large airways ensures that particles in excess of 10 μm in diameter are deposited on the mucus-coated surfaces of the nose, pharynx, trachea, and descending airways. In turn, mucus, its ensnared particulates, and dissolved solutes are constantly wafted toward the pharynx by the coordinated beating of ciliated airway epithelial cells where their removal is aided by coughing, sneezing, and swallowing. In addition to the biophysical

Table 12-1 Some Constituents of Airway Epithelial Fluid

Lysozyme	Statherin

properties of mucus in innate host defense of the airways, the gel and pericellular liquid phases also contain an array of antimicrobial peptides and proteins, antioxidants, anti-proteases, and specific *immunoglobulin A* (IgA) antibodies (Table 12-1), all of which are maintained at a modestly acidic pH (pH 6.6).⁴ Principal among airway antimicrobial peptides in humans are salt-sensitive cysteine-rich cationic β-defensins and the cathelicidin LL37/hCAP18.⁵⁻⁹ β-defensin-1 is constitutively secreted by airway epithelia and accumulates in airway surface liquid at microgram per milliliter concentrations.¹⁰ Other β-defensins and LL37/hCAP18 are inducibly expressed following exposure to LPS and other proinflammatory mediators.¹¹⁻¹³ Antimicrobial proteins, including lactoferrin and lysozyme, are also present in airway epithelial secretions and contribute to the maintenance of normal airway sterility.^{14,15}

The conducting airways are lined with ciliated and secretory epithelial cells that serve a key role in the initial evaluation of the surfaces of large particles with which they come into contact. In addition, a network of DCs resides throughout the airway epithelium and continuously samples the airway lumen (see Fig. 12-1). DCs are particularly abundant in the trachea and large conducting airways where most large particulates are deposited. In the absence of PAMPs, DCs capture airway antigens and migrate to regional lymph nodes where, for harmless antigens, they induce CD4⁺ and CD8⁺ T-cell tolerance.

In contrast to large particles, particles smaller than 5 μm in diameter are able to descend the entire tracheobronchial tree and lodge at bronchiolar-respiratory duct junctions or deposit onto the surfactant-rich surfaces of the alveoli. While sharing many similarities with innate protection of the airways—for example, the presence of antioxidants, antiproteases, and antimicrobial enzymes—additional innate protection of the alveoli is afforded by the presence of resident alveolar macrophages and the lung-specific collectins, *surfactant protein A* (SP-A) and *surfactant protein D* (SP-D) (see Fig. 12-1). In addition to expressing *Toll-like receptors* (TLRs), resident alveolar macrophages express *scavenger receptors* (SRs) that participate in the phagocytosis of microbial and nonmicrobial particles. SP-A and SP-D are secreted PRRs and are capable of binding to microbial PAMPs, leading to opsonization and phagocytosis by alveolar macrophages and intraseptal DCs, which then either crawl into the airways and move up the mucociliary escalator or migrate to regional lymph nodes, respectively. In the absence of PAMPs, resident alveolar macrophages also play

Table 12-2 Representative Genes Activated by Pattern Recognition Receptors

CXCL CHEMOKINES <i>CXCL1, CXCL2, CXCL4, CXCL9, CXCL10, CXCL11</i>
CCL CHEMOKINES <i>CCL1, CCL2, CCL7</i>
CYTOKINES <i>TNF-α, IL-1β, TGF-β, IL-10</i>
TLRS <i>TLR2, TLR4, TLR9</i>
PROSURVIVAL <i>BCL2, cIAP1, cIAP2, BCL10</i>
ANTIMICROBIAL β-defensins, cathelicidins
DC MATURATION <i>CD40, CD80, CD86, MHC Class II, Class II</i>

Transcription of most of these genes is initiated by the activation of NFκB and/or AP1. NFκB activation is initiated by most PRRs.
AP1, activator protein-1; CCL, CC chemokine ligand; CXCL, CXC chemokine ligand; DC, dendritic cell; MHC, major histocompatibility complex; NFκB, nuclear factor-κB; PRR, pattern recognition receptor; TLR, Toll-like receptor.

an important role in suppressing inflammation and adaptive immunity, thereby protecting the alveoli from unwanted responses to harmless inhaled particulates. SP-A and SP-D also play a key role in suppressing inflammation in the absence of PAMPs through tonic signaling effects on resident alveolar macrophages. Thus the innate immune system not only protects the lungs from harmful microbes, but also prevents inflammation, injury, and activation of the adaptive immune system in the steady state and in response to harmless inhaled particulates.

How then, do the airways and alveoli respond to the presence of potentially harmful microbes? As illustrated in Figure 12-1, resident airway and alveolar macrophages, DCs, and airway and alveolar epithelial cells are capable of recognizing different PAMPs through their repertoires of cell surface and intracellular PRRs, and by the interaction of PAMP-bound secreted PRRs with specific receptors on epithelial cells, macrophages, and DCs. In turn, these interactions induce signaling responses that promote the expression of an array of innate response genes (Table 12-2). These gene products collectively promote the migration of PMNs and monocytes from the pulmonary circulation into the air spaces, facilitate changes in endothelial and epithelial permeability to enhance inflammatory cell transmigration into the air spaces, and initiate the expression of specific genes involved in microbial killing. In addition, DCs phagocytose PAMP-expressing microbes, mature, and migrate to regional lymph nodes (see Fig. 12-1). During this process, ingested microbial products are digested, captured by *major histocompatibility complex* (MHC) class II molecules, and displayed on the DC plasma membrane together with co-stimulatory molecules such as CD40, CD80, and CD86 for effective presentation to naive CD4⁺ and CD8⁺ T cells. Following activation and expansion in regional lymph nodes, effector CD4⁺ and CD8⁺ T cells then migrate back to

the site of microbial infection to augment specific host defense through their ability to activate macrophages and other effector cells.

In summary, innate immune mechanisms involving the airway and alveolar epithelium, secreted antimicrobial enzymes, PRRs and peptides, mucus and mucociliary transport, and resident macrophages and DCs protect the lung against inhaled microbial and nonmicrobial particulates to maintain lung homeostasis. During steady-state conditions, the innate immune system actively suppresses inflammation and promotes tolerance to commonly inhaled harmless particulates. However, above a certain threshold and/or upon sensing the presence of PAMPs, additional mechanisms are activated to protect the lungs by promoting inflammation and adaptive immunity and by establishing communication and cooperation between these systems. Although it is convenient to think of these events separately, innate host responses to both harmless nonmicrobial particulates and harmful microbes take place simultaneously and silently to maximize lung health and protection.

INNATE RECOGNITION IN THE LUNG

With this broad overview of the key elements in innate host defense of the lung and their connections to adaptive immunity, we now consider how microbes are recognized by resident and recruited lung cells. For this purpose, we specifically focus on the mechanisms of recognition by PRRs that are expressed by epithelial cells, macrophages, and DCs or are present in airway or alveolar surface liquids.

SECRETED PATTERN RECOGNITION RECEPTORS

Secreted PRRs have evolved to serve as bridges between certain PAMPs and specific receptors for these molecules. In the lung, secreted PRRs have particularly important roles in innate protection of the alveolar surfaces.

Collectins

The collectins are a family of secreted PRRs; SP-A and SP-D are collectins that are uniquely expressed in the distal lung.¹⁶ All members of the collectin family are characterized by the presence of a cysteine-rich N-terminal noncollagenous domain, a collagen-like domain, an α -helical coiled-coil neck domain, and a globular C-type lectin domain (also called the “carbohydrate recognition domain” [CRD]) that interacts with microbial PAMPs (Fig. 12-2A). At baseline, SP-A and SP-D suppress inflammation (see later) (shown for SP-D in Fig. 12-2B); in the presence of a variety of PAMPs, SP-A and SP-D stimulate microbial phagocytosis, the production of reactive oxidant species, and the expression of proinflammatory cytokines (see Fig. 12-2C).^{17,18} A proinflammatory response is activated when PAMP-bound SP-A and SP-D interact with macrophages via their collagenous tails through CD91¹⁹⁻²¹ (see Fig. 12-2C). Consistent with these findings, SP-A-deficient and SP-D-deficient mice have increased susceptibility to pulmonary infection with *Pseudomonas aeruginosa* and *Staphylo-*

coccus aureus,^{22,23} emphasizing the important contribution of these lung-specific collectins to innate lung host defense. Additional information on SP-A and SP-D can be found in Chapter 8.

The lung is remarkable in that it is capable of eliminating harmful pathogens from the alveolar surfaces while actively suppressing unwanted and potentially harmful inflammatory responses to harmless inhaled materials. Several studies have shed new light on this dichotomy by revealing an additional role for SP-A and SP-D in the tonic suppression of lung inflammation. When initially created, SP-D-deficient mice were found to have increased numbers of foamy, activated alveolar macrophages, suggesting that SP-D may somehow tonically suppress lung macrophage activation and lung inflammation (see Fig. 12-2B).²⁴ As illustrated in Figure 12-2C, in the steady state (i.e., in the absence of PAMPs), SP-D and SP-A interact with alveolar macrophages via their globular head groups and signal via signal-inhibitory regulatory protein α to suppress proinflammatory responses.¹⁹ Thus SP-A and SP-D, through their ability to interact under different circumstances with CD91 and signal-inhibitory regulatory protein α , play a pivotal role in the maintenance of the antiinflammatory environment of the alveoli under steady-state conditions, while promoting an inflammatory and innate response when microbes are sensed. Other studies suggest that lipid and phospholipid constituents of surfactant also contribute to maintenance of the antiinflammatory environment of the alveoli.²⁵

Complement

The complement system functions as a pattern recognition system and a bridge to adaptive immunity through its ability to recognize repetitive structures on some microbes and on the Fc region of immunoglobulin G (IgG) and immunoglobulin M (IgM) antibodies. Complement activation is important in lung innate immunity because it promotes the opsonization of microbes and the generation of the potent chemotactic factor C5a, which in turn assists in the recruitment of phagocytic cells. Complement components of the classical, alternative, and mannose-binding lectin activation pathways are present in lung airway and alveolar fluids²⁶⁻²⁸ and are synthesized by alveolar type II cells, macrophages, and DCs.^{15,29-31} Many microbes can directly activate the alternative complement pathway, resulting in the covalent attachment of C3b to the microbial cell wall. Microbes expressing cell wall-associated mannose-rich polysaccharides can also bind mannose-binding lectin and activate the mannose-binding lectin pathway to promote C3b attachment to the microbial cell wall. Phagocytic cells, especially macrophages, PMNs, and DCs, express various receptors for C3b and C3bi and, together with other receptors, phagocytose and kill complement-opsonized microbes.

Pentraxins and Other Secreted Pattern Recognition Receptors

The pentraxins, including C-reactive protein, serum amyloid P, and pentraxin 3, also recognize PAMPs on microbes and activate the complement system to assist in microbial removal by phagocytic cells.^{32,33} Similarly, ficolins promote phagocytosis and complement activation by

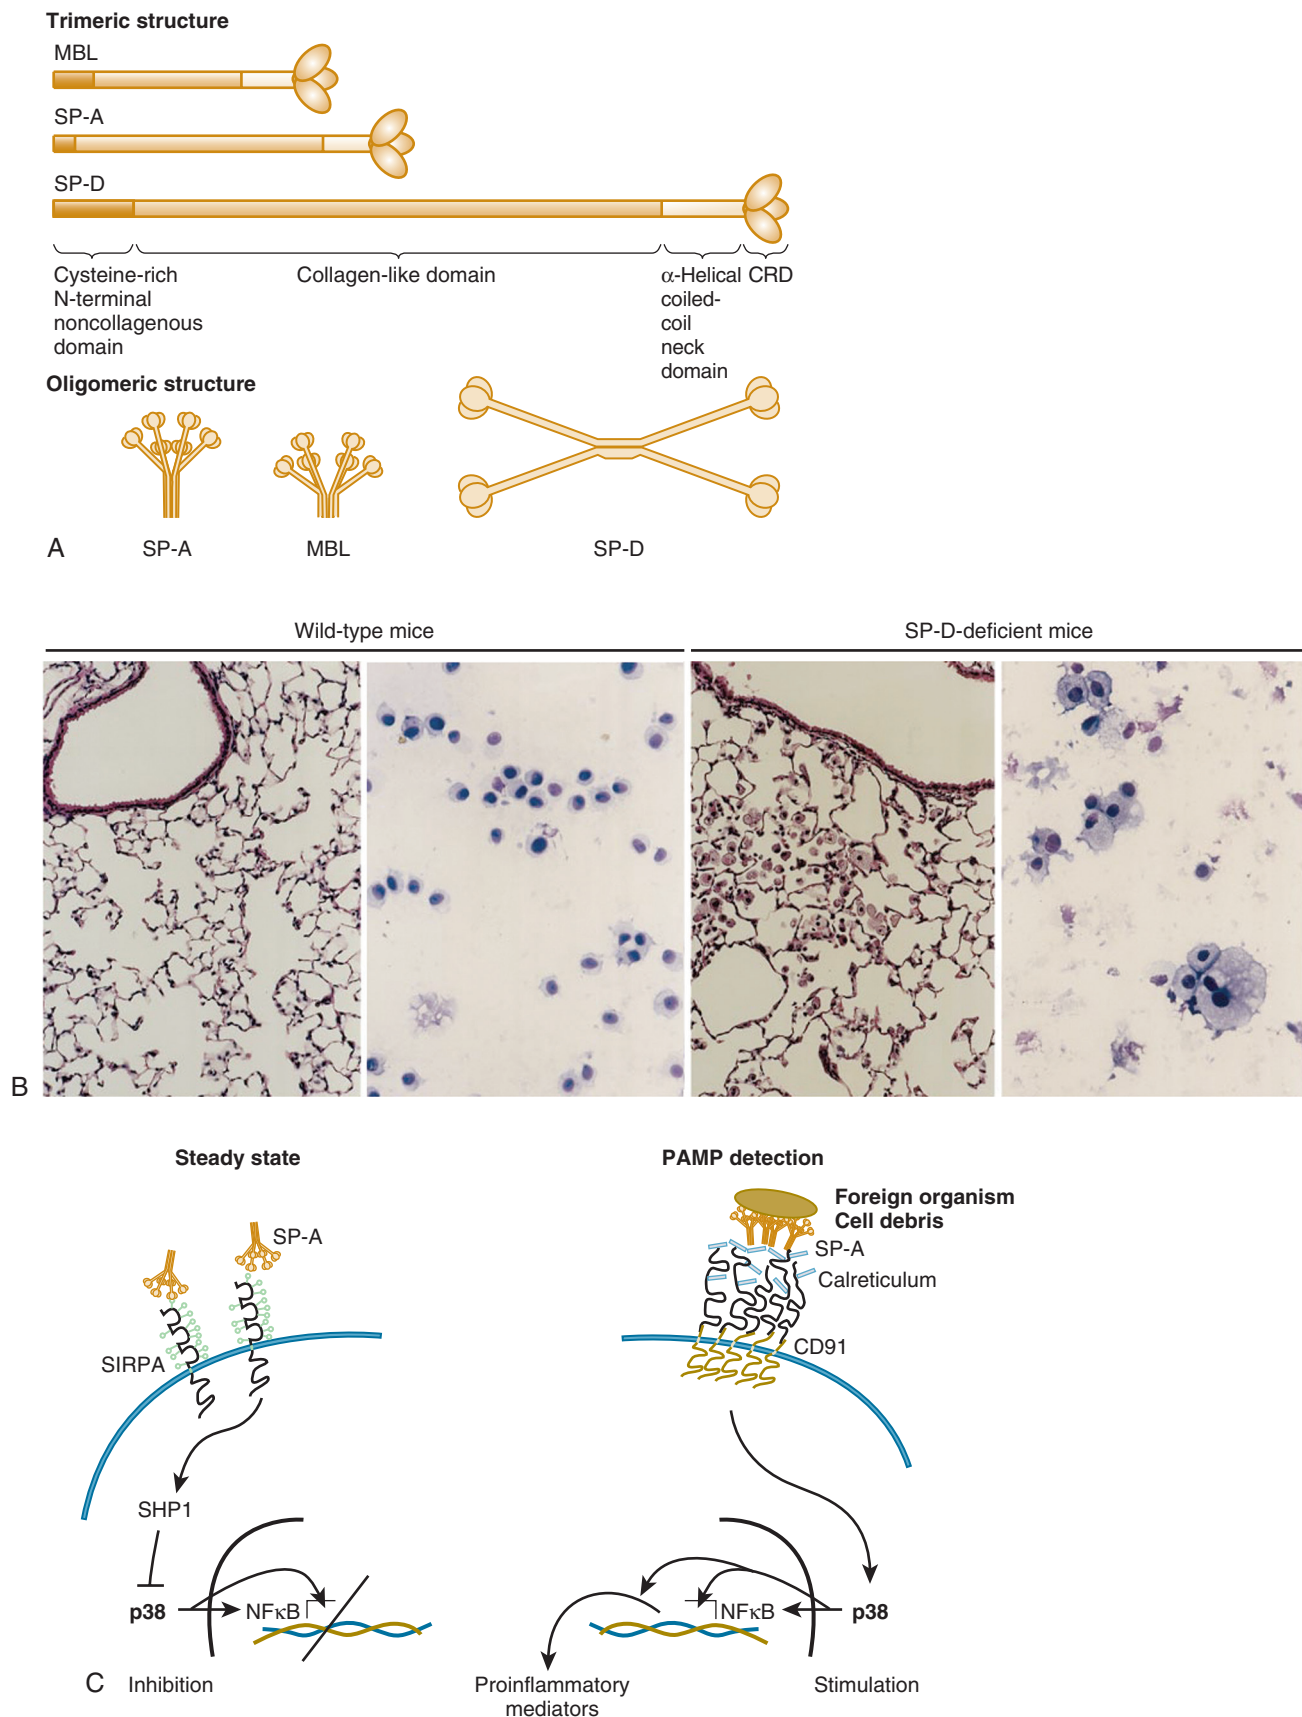

Figure 12-2 Pulmonary collectins, especially surfactant protein A (SP-A) and surfactant protein D (SP-D), play a key role in suppressing inflammation in the absence of pathogen-associated molecular patterns (PAMPs) while stimulating inflammation in the presence of PAMPs. **A**, Structure of pulmonary collectins. **B**, The importance of SP-D in tonic suppression of lung inflammation is illustrated by the spontaneous proinflammatory phenotype of SP-D-deficient mice. **C**, Tonic suppression of inflammation is mediated by the binding of collectins to signal-inhibitory regulatory protein α (SIRP α) via their head groups, whereas activation of inflammation is mediated when PAMP-bound collectins interact with CD91 via their collagenous tail regions. binding to the gram-positive bacterial cell wall components *N*-acetylglucosamine and lipoteichoic acid.³⁴

CELLULAR PATTERN RECOGNITION RECEPTORS

Different families of PRRs have evolved to enable the host to sense the presence of PAMPs in extracellular, endosomal, and cytoplasmic compartments, in each of the lineages involved in lung innate immunity (Fig. 12-3). Transmembrane cell surface and endosome-associated PRRs include the TLRs widely expressed on epithelial cells, macrophages, PMNs, and DCs (see Fig. 12-3A), SRs primarily expressed on macrophages (see Fig. 12-3B), and C-type lectin receptors mainly expressed on DCs (see Fig. 12-3C). Cytoplasmic PRRs are composed of *nucleotide-binding and oligomerization domain* (NOD)-like receptors (NLRs) and RNA helicases of the *retinoic acid-inducible gene* (RIG) family. Each of the cytoplasmic PRRs has evolved as a strategy to alert the host to the presence of PAMPs within the cytoplasm, as often happens during the intracellular replication of facultative bacteria and viruses.

Plasma Membrane and Endosomal Pattern Recognition Receptors

Toll-like Receptors. TLRs are expressed on airway and alveolar epithelial cells, macrophages, PMNs, and DCs.³⁵⁻³⁸ Thirteen TLRs have been described in mice (Tlr1 to Tlr13) and 10 in humans. Significant progress has been made in understanding the functions and downstream signal transduction pathways of TLRs.³⁹⁻⁴² TLRs can be divided into those expressed on the cell surface (TLR1, 2, 4, 5, 6, and 11) and those expressed in intracellular compartments (TLR3, 7, 8, and 9) (see Fig. 12-3A). TLRs also recognize endogenous ligands called *danger-associated molecular patterns* (DAMPs), including heat shock proteins, low-molecular-weight hyaluronan, heparin sulfate, fibronectin, high-mobility-group box-1, protein and low-density lipoproteins. Recognition of DAMPs by TLRs and other PRRs is usually associated with the initiation of sterile inflammation. Surface TLRs recognize a wide variety of PAMPs, whereas intracellular TLRs mainly recognize nucleic acid-based PAMPs. TLRs not only recognize their individual cognate PAMPs but also combine with other TLRs to form heteromeric complexes that recognize a broader range of PAMPs.⁴²⁻⁴⁵ For example, TLR1 associates with TLR2 to recognize microbial lipopeptides,⁴⁵ TLR2 and TLR4 recognize the LPS-binding protein/myeloid differentiation protein-2 complex when presented by CD14, and TLR2 recognizes broad patterns of lipoproteins in concert with either TLR1 or TLR6.⁴⁶ TLR5 recognizes flagellin and is particularly important in the response of airway epithelial cells to *P. aeruginosa* infection. Similarly, TLR6 can functionally associate with TLR2 to recognize a variety of microbial lipopeptides and peptidoglycans from gram-positive bacterial cell walls.⁴⁷ TLR3, 7, 8, and 9 are not highly expressed at the cell surface but are expressed intracellularly in endosomal and endoplasmic reticulum membranes, where they sense nucleic acids that are released from ingested and digested microbes.³⁹⁻⁴² TLR3 recognizes viral double-stranded RNA and induces the production of type I *interferons* (IFNs) (IFN- α /IFN- β),⁴⁸ which in turn play a vital role in antiviral immunity and in DC maturation.⁴⁹ TLR7 recognizes single-

stranded RNA from viruses, whereas TLR9 recognizes unmethylated cytosine-guanosine motifs in microbial DNA.^{50,51}

Scavenger Receptors. The first macrophage SR was described by Goldstein and colleagues⁵² and Brown and associates⁵³ and was shown to bind and internalize acetylated low-density lipoprotein. Since then, multiple SRs have been identified and shown to play diverse roles in the phagocytosis of a variety of particles and molecules ranging from bacteria to lipids (see Fig. 12-3B). The SR family comprises eight classes (A to H), of which class A (SRA) and class B (SRB) are primarily involved in innate immunity through their ability to recognize and promote phagocytosis of a wide range of bacteria. Members of the SR-A and SR-B subfamilies are abundantly expressed on macrophages but do not appear to be expressed by airway or alveolar epithelial cells. The lack of expression on epithelial cells is in keeping with the notion that, during exposure to inhaled microbes and particles, the lung epithelium has evolved mechanisms to respond to PAMPs by promoting inflammation but not to engage in phagocytosis, leaving this activity to professional phagocytes.

Class A SRs are homotrimeric type II transmembrane proteins (extracellular C-terminal). SRA exists as two splice variants (SRAI and SRAII) of a single gene whose primary function is to promote the phagocytosis of a range of non-opsonized bacteria, including *S. aureus*, *Streptococcus pneumoniae* and *Escherichia coli*.⁵⁴ SRA-deficient mice have increased susceptibility to systemic infections with *S. aureus* and *Listeria monocytogenes*^{55,56} and to pulmonary infections with *S. pneumoniae*.⁵⁷ *Macrophage receptor with collagenous structure* (MARCO) is an additional class A SR that is involved in innate pulmonary host defense against *S. pneumoniae*.⁵⁸ Down-regulation of MARCO by IFN- γ increases susceptibility to *S. pneumoniae* in mice and may contribute to the development of pulmonary bacterial pneumonias following influenza infections.⁵⁹ MARCO may also play a role in dampening pulmonary inflammation because MARCO-deficient mice exhibit increased lung inflammation in response to inhaled silica and oxidants.^{60,61}

Class B SRs are primarily represented in the lung by CD36. CD36 is expressed on monocytes, macrophages, DCs, and vascular endothelium.⁶²⁻⁶⁴ Like class A SRs, CD36 has been implicated in PAMP recognition⁶⁵ and in the phagocytosis of *S. aureus*.^{66,67} However, whereas CD36 deficiency in mice results in impaired host defense against *S. aureus*,⁶⁵ the absence of CD36 in humans, via a natural genetic deficiency, is not associated with a pulmonary phenotype.⁶⁸

C-Type Lectin Receptors. *C-type lectin receptor* (CLR) domains are also present in a family of cell surface receptors that play an important role in the function of DCs and macrophages (see Fig. 12-3C). CLRs recognize high-density carbohydrate-based PAMPs on microbial cell walls and viral coats. Carbohydrate binding can be divided into mannose and galactose specificity.⁶⁹ Type I CLRs include *dendritic and thymic epithelial cell-205* (DEC205) and macrophage mannose receptor, and type II CLRs include dendritic cell-specific *intracellular adhesion molecule* (ICAM3), *dendritic cell-specific intercellular adhesion molecule-grabbing nonintegrin* (DC-SIGN), and *dendritic cell-specific receptor-1* (DECTIN1).

As we discuss later, studies in mice bearing targeted disruptions of CLR genes have emphasized their importance in innate host defense and particularly in DC maturation and antigen presentation.

DEC205 is a type 1 transmembrane receptor protein found on a variety of DC subsets and macrophages.⁷⁰ The natural carbohydrate ligands remain largely uncharacterized, though the receptor has been shown to induce the endocytosis of experimental antigen–anti-DEC205 receptor complexes and promote their delivery to endosomes before antigen processing and presentation. When DCs are treated with the antigen–anti-CD205 fusion protein alone, they induce tolerance to the antigen by deleting specific CD4⁺ and CD8⁺ T cells and by promoting the development of *T regulatory* (Treg) cells.⁷¹ In the presence of an inflammatory stimulus, DCs exposed to the antigen–anti-DEC205 fusion proteins promote long-lived immunity mediated by Ag-specific CD4⁺ and CD8⁺ T cells.^{72,73} Antigens delivered by targeting DEC205 may be presented in association both with MHC class II molecules and by cross-presentation with MHC class I molecules.^{74–76} Furthermore, a recent study showed that DEC205 mediates the uptake of self-antigens via the endocytosis of apoptotic cells, thereby providing a plausible mechanism for the cross-presentation of self-antigens resulting in the induction of both central and peripheral tolerance.⁷⁷

DECTIN1 was initially thought to be expressed specifically on DCs but was later shown to be expressed also on macrophages, monocytes, PMNs, and some T-cell subsets.^{78,79} DECTIN1 specifically recognizes β -(1,3)-linked glucans and β -(1,6)-linked glucans⁸⁰ and is thought to play a key role in the nonopsonic phagocytosis of a number of pathogenic yeasts, fungi, and bacteria by macrophages and DCs.⁸¹ Ligation of DECTIN1 also stimulates the production of an array of proinflammatory cytokines, oxidants, and lipid mediators.^{82–86}

DC-SIGN is also a type II CLR^{87,88} but differs from DECTIN1 by its specificity for microbial mannose-rich carbohydrates.^{87,89–91} DC-SIGN is important in DC trafficking and DC–T-cell interactions through its ability to interact with ICAM3 and ICAM2, respectively. DC-SIGN is also expressed on the surface of a subset of peripheral blood and lung BDCA-2⁺ *plasmacytoid DCs* (pDCs) and resident alveolar macrophages.⁹² Interestingly, increased expression of DC-SIGN by alveolar macrophages has been reported in response to stimulation with interleukin-13 (IL-13), suggesting a possible role for DC-SIGN⁺ cells in the pathogenesis of *type 2 T helper* (Th2)–mediated lung diseases.⁹²

Cytoplasmic Pattern Recognition Receptors

Nucleotide-Binding and Oligomerization Domain-like Receptors. In humans, NLRs are a family of 22 intracellular PRRs that have evolved to sense PAMPs in the cytoplasm of most cells. Cytoplasmic PAMPs recognized by NLRs include bacterial peptidoglycans and flagellin from gram-positive and gram-negative bacteria as well as microbial toxins such as *Bacillus anthracis* lethal factor.^{93–95} Earlier, we briefly introduced DAMPs as a collection of nuclear and cytoplasmic molecules, including high-mobility-group box-1 protein, adenosine triphosphate, *nicotinamide adenine dinucleotide* (NAD⁺), and adenosine, that are released following tissue injury.⁹⁶ Recent studies have also shown that,

though not technically DAMPs, uric acid and crystalline silica are also sensed by NLRs and, like PAMPs, initiate sterile inflammatory responses.^{97–99} In turn, the recognition of cytoplasmic PAMPs and DAMPs by NLRs activates an array of signal transduction pathways that lead to the production of proinflammatory cytokines. NLRs also induce the assembly of intracellular protein-protein complexes called “inflammasomes,”^{100–103} which stimulate IL-1 β production and initiate several different forms of programmed cell death, including apoptosis, necrosis, pyroptosis, and pyronecrosis.¹⁰⁴ NLRs may also play a role in the maturation of immature DCs after exposure to PAMPs or cytokines.¹⁰² The precise mechanisms by which NLRs signal is an area of intense investigation, but studies show that NLRs participate in the formation of three distinct inflammasomes, including the NALP1- and NALP3-containing inflammasomes and interleukin-1 β -converting enzyme protease-activating factor-containing inflammasomes.^{93,101} Although the role of NLRs in a variety of human disorders has been characterized, the complete role of these molecules in lung homeostasis and defense is not yet fully understood. More information about NLR structure and function is available in several recent reviews.^{93,95,101,104–110}

Retinoic Acid–Inducible Gene-1–like Receptors. The last group of cytoplasmic PAMP sensors is the RIG1-like receptors that have evolved to detect the presence of RNA from RNA viruses and replicating DNA viruses. Three family members, RIG1, myeloma-differentiation associated gene 5, and laboratory of genetics and physiology 2, have been identified. RIG1 has been shown to recognize viral RNA sequences from several viruses and is involved in the response of lung epithelial cells to influenza virus.^{111,112} In contrast, myeloma-differentiation associated gene 5 has been shown to respond to polyriboinosinic:polyribocytidylic acid and picornoviruses.¹¹³ Upon sensing viral RNA sequences, RIG-like family members promote the expression of type I IFNs and proinflammatory cytokines,¹¹⁴ thereby inducing and augmenting host and lung innate immunity.

SUMMARY

Secreted, plasma membrane, endosomal, and cytosolic PRRs provide remarkable flexibility in innate protection of the lung. In the descending airways, plasma membrane PRRs, especially TLRs, are poised to sense PAMPs but are generally unable to phagocytose PAMP-containing microbes. However, TLR signaling in airway epithelial cells results in the production of proinflammatory mediators, especially chemokines and cytokines, which call in PMNs and macrophages to the site of PAMP detection to enable microbial clearance. In addition, intraepithelial DCs constantly sample the airway lumen to maintain immunologic tolerance to commonly encountered antigens that do not express PAMPs, while remaining poised to activate the adaptive immune system once PAMPs are sensed. The alveoli are also protected by epithelial cells, DCs, and resident alveolar macrophages that also sense PAMPs via plasma alveolar PRRs. However, in the alveoli, two additional levels of protection exist. First, secreted PRRs, especially SP-A and SP-D, protect the alveolar surfaces by tonically suppressing unwanted

inflammation in the steady state, while remaining poised to stimulate innate responses in the presence of PAMPs. Second, resident alveolar macrophages express an additional array of PRRs, especially SRs that promote the phagocytosis of microbes and other particulates. It seems reasonable to suggest that, in the steady state, the innate immune system responds to inhaled particulates and microbes continuously, but silently. In the next section, we discuss how ligation of these various PRRs activates and regulates innate host defense responses in lung cells.

EFFECTOR MECHANISMS

The cell types that are primarily responsible for innate protection of the lung in the steady state are (1) airway and alveolar epithelial cells and (2) macrophages and DCs. Additionally, in response to the initial activation of these cells, PMNs, which though not an abundant cell type in the steady state, are rapidly recruited to augment lung phagocyte numbers once the presence of PAMPs is detected. In the following section, we review the origin and functions of these resident and recruited cells in innate protection of the lung.

EPITHELIUM

The lung epithelium has an important role in host defense against microbes that pass through the glottis and reach the conducting airways and gas-exchange parenchyma. The conducting airways of the lower respiratory tract are lined by ciliated columnar epithelial cells down to the terminal airways; these cells become nonciliated in the respiratory bronchioles. In contrast, the alveolar epithelium consists of flattened type I epithelial cells that form most of the alveolar surface and type II cuboidal epithelial cells that produce surfactant and surfactant-related proteins and project into the subepithelial structures of the lungs. The classic antimicrobial defense mechanism in the conducting airways is the mucociliary system, which moves microbes deposited on the airway epithelial surface upward and out of the lungs. In addition to this physical removal system, the airway and alveolar epithelium participate actively in the innate defense of the lungs, with the major goal of protecting the critical gas-exchange surface from microbial invasion.¹¹⁵ The mucociliary system provides for the removal of all particles that deposit on the airway epithelium, and the clearance times in the trachea and proximal airways are measured in minutes (see Video 11-3). The cilia on the epithelial surface beat in coordinated waves, directing the movement of particles upward toward the larynx. Epithelial cell activation is not required for optimal ciliary beating, although beat frequency can be speeded by β -agonists and slowed by opiates and other drugs.¹¹⁶ Additional information on mucociliary clearance can be found in Chapter 11.

The mucociliary system and antimicrobial constituents of airway epithelial fluid discussed in the “Overview of the Components of Lung Innate Immunity” section (see Table 12-1) can be thought of as constitutive host defenses, because they do not depend on specific microbial recognition mechanisms and do not need activation. However, the

airway and alveolar epithelium also participate in innate immune mechanisms in that they express bacterial recognition molecules (PRRs) common to innate immune cells and can produce an array of proinflammatory mediators that recruit leukocytes into the airways directly through the airway and alveolar epithelial walls. Bacterial products stimulate the airway epithelium to produce chemotactic signals that recruit inflammatory cells into the airways. Endogenous cytokines also stimulate airway and alveolar epithelial cells to amplify leukocyte migration. Bacterial LPS stimulates ciliated airway epithelial cells to produce CXC and CC chemokines, which recruit PMNs and monocytes, respectively, into the airway lumen.¹¹⁷ Airway epithelial cells also produce IL-1 β , IL-6, IL-8, RANTES (regulated on activation, normal T-cell expressed and secreted), *granulocyte-macrophage colony-stimulating factor* (GM-CSF), and *transforming growth factor- β* (TGF- β).¹¹⁵ As with other cells involved in innate immunity, airway epithelial cells produce cytokines via the activation of transcription factors, including *nuclear factor- κ B* (NF κ B), activator protein-1, and nuclear factor interleukin 6.¹¹⁸ Interestingly, noninfectious environmental agents like ozone,¹¹⁹ asbestos,¹²⁰ diesel exhaust particles,¹²¹ and air pollution particles¹²² all lead to NF κ B activation in airway epithelial cells under experimental conditions, which is typically followed by IL-8 production and release. Airway epithelial cells also recognize unmethylated bacterial DNA via TLR9, leading to NF κ B activation and production of IL-6, IL-8 and β_2 -defensin in the airways.¹²³ Unlike airway epithelial cells, alveolar epithelial cells do not respond directly to LPS but do produce chemokines in response to the *tumor necrosis factor- α* (TNF- α) and IL-1 β secreted by alveolar macrophages in response to bacteria or their products.

The critical role of the lung epithelium in innate immunity and microbial defense has been supported by studies using transgenic mice. When a dominant negative I κ B construct was expressed in the distal airway epithelial cells of mice, thereby preventing NF κ B activation, airway PMN recruitment in response to inhaled LPS was impaired.¹²⁴ This finding supports the importance of bacterial recognition by distal airway epithelial cells in vivo and shows that epithelium-derived cytokines produced by the NF κ B pathway probably are just as important as macrophage-derived cytokines in driving innate inflammatory responses in the airways and alveolar spaces. Hajjar and colleagues¹²⁵ created bone marrow chimeras in which either myeloid (leukocytes) or nonmyeloid (epithelial) cells lacked Myd88, a key adapter molecule required for signaling via all TLRs except TLR3. It turned out that *nonmyeloid* deficiency of Myd8 impaired bacterial clearance more than *myeloid* deficiency. Specifically, the mice lacking Myd8 (and therefore lacking TLR signaling) in nonmyeloid cells, including the airway and alveolar epithelium, had markedly impaired clearance of *P. aeruginosa*, whereas mice with or without Myd8 in myeloid cells had normal bacterial clearance. This surprising result further supports the important role of the airway and alveolar epithelium in bacterial recognition and clearance from the lungs, a role that is perhaps equivalent to that of resident and recruited leukocytes.

Innate immune responses in the airway epithelium can generate or influence adaptive responses. For example, recognition of β -(1,3)-glucan in house dust mites stimulates

Figure 12-4 Neutrophils use several mechanisms to kill microbes. BPI, bacterial permeability-increasing protein; LL37, cathelicidin; MMP, matrix metalloproteinase; MPO, myeloperoxidase; NET, neutrophil extracellular trap. (Modified from Nathan C: Neutrophils and immunity: challenges and opportunities. *Nat Rev Immunol* 6:173–182, 2006.)

the production of CCL20, a chemokine that recruits immature DCs into the airways.¹²⁶ The airway epithelium can directly influence the function of lung DCs, inducing adaptive Th2 responses that are thought to be important in the pathogenesis of asthma, and LPS responses in the airway epithelium are involved in some DC-driven Th2 cell responses.¹²⁷ Airway epithelial cells produce thymic stromal lymphopoietin, GM-CSF, IL-1 β , IL-25, IL-33, and osteopontin, all of which activate DCs.¹²⁸

An emerging concept is that deliberate stimulation of innate immunity in the airways and air spaces produces broad enhancement of antimicrobial defenses. Exposure of mice to a crude extract of nontypeable *Haemophilus influenzae* bacteria via aerosol initially stimulated innate immunity and then protected the mice from lethal infection with *S. pneumoniae*.¹²⁹ This was associated with enhanced production of lysozyme, lactoferrin, and defensins in the lungs. Similarly, exposure to this crude bacterial extract protected mice from *S. aureus*, *P. aeruginosa*, and the fungus *Aspergillus fumigatus*.¹³⁰ Thus prestimulation of innate immune mechanisms in the airway and perhaps alveolar epithelium enhances the antimicrobial activity and host defense of the lungs against a broad array of bacteria and fungi. The implication is that deliberate low-level stimulation of innate immunity in the lungs could be used as a protective strategy; however, the emerging recognition of the important role of lung epithelial innate immunity in stimulating and regulating adaptive immune mechanisms raises the possibility that such a strategy might have unexpected effects.

Thus innate immune mechanisms in the airways stimulate endogenous defenses by enhancing production of airway defensins and other antimicrobial products, by stimulating PMN and monocyte recruitment into the airways to augment antimicrobial defenses, and by setting the stage for DCs and Th2-mediated adaptive immune responses that could be important in the pathogenesis of allergic lung diseases.

POLYMORPHONUCLEAR LEUKOCYTES

PMNs serve as the immediate effector arm of the innate immune system.^{131,132} PMNs are produced from progenitor

cells in the bone marrow, circulate for a short time in the bloodstream, and migrate to sites of tissue inflammation in response to signals produced by local innate immune mechanisms. Mature PMNs are released from the marrow in response to granulocyte colony-stimulating factor and other stimuli and circulate for up to 6 to 8 hours. The bone marrow releases between 10^9 and 10^{10} PMNs each day, and marrow release can increase severalfold in response to acute signals from the lungs and other tissues. PMNs contain several different kinds of cytoplasmic granules, which contain an array of proteins (Fig. 12-4). Small specific granules serve as a source of new membrane and fuse with the leading edge of the cell during migration. Primary (azurophilic) granules contain myeloperoxidase, which accounts for the green color of pus, bacterial permeability-increasing protein, PMN elastase, matrix metalloproteinases, other proteinases, and defensins.

Circulating PMNs are spherical, with a diameter of approximately 8 μm and must deform to make their way through the capillary microcirculation in the lungs and other organs. PMNs bear surface adhesion molecules that recognize carbohydrate and protein moieties expressed on activated endothelial cells. In the systemic circulation, PMNs migrate into tissue through postcapillary venules in a four-step process by (1) weakly adhering to the venular endothelium, (2) rolling along the endothelial surface, (3) arresting on the endothelial surface, and (4) migrating between endothelial junctions into tissue in response to local chemotactic gradients.^{133,134} This systemic paradigm is different in the lungs, where the pulmonary capillaries slow the transit of PMNs because of the small cross-sectional capillary diameter.^{135,136} This produces a reservoir of capillary PMNs that are poised to respond directly to signals from the innate immune system in the air spaces. When bacteria or their products such as gram-negative LPS circulate in the bloodstream, PMNs undergo activation with cytoskeletal rearrangements that cause stiffening,¹³⁷ promoting increased entrapment of PMNs in the pulmonary capillaries.

When innate immunity is activated in the lungs, chemotactic factors are produced by resident alveolar macrophages and activated epithelium, which create soluble and tissue-fixed gradients that recruit PMNs into the alveolar

spaces. Leukotriene B₄ is a product of arachidonic acid metabolism in alveolar macrophages that produces an immediate and short-lived soluble gradient that recruits PMNs into the air spaces but dissipates within minutes.^{138,139} Release of leukotriene B₄ is closely followed by the release of IL-8, a chemokine that binds to heparin residues on tissue matrix, creating a tissue reservoir that promotes long-lived gradients.^{140,141} IL-8 is the dominant member of a group of CXC chemokines, which also include GRO- α , GRO- β , and GRO- γ , and ENA-78. The CXC chemokines have a C-X-C sequence at the N-terminus, which provides PMN specificity, and an N-terminal Glu-Leu-Arg peptide sequence, which is important in chemotactic receptor binding. The CXC chemokines recruit PMN to sites of inflammation, whereas chemokines with the CC N-terminal sequence recruit monocytes. IL-8 and related chemokines probably reach the endothelial luminal surface by diffusion from alveolar fluids and bind to endothelial cell surface glycosaminoglycans to create a fixed local signal that guides PMNs sequestered in pulmonary capillaries into the air spaces. Whereas PMNs bear a single receptor for leukotriene B₄, they express two different receptors with differing affinity for IL-8. The low-affinity receptor (CXCR2) is thought to recruit PMNs to sites of inflammation, whereas the high-affinity receptor (CXCR1) is thought to guide PMN migration into the tissues. The low-affinity receptor is shed from the surface of circulating PMNs in sepsis, leaving the high-affinity CXCR1 receptor as the dominant IL-8 receptor.¹⁴² This suggests that a CXCR1 receptor-targeted strategy could be effective in limiting PMN inflammation in patients with sepsis. PMNs also have receptors for the complement component C5a and for formylated peptides produced by bacteria in the air spaces, so that endogenous as well as exogenous signals attract PMNs to sites of inflammation. The diversity of chemotactic stimuli recognized by PMNs promotes the formation of combinatorial gradients that guide PMN migration toward localized sites of inflammation in the lungs and other tissues.¹⁴³

In the systemic circulation, PMN migration into tissues depends on the integrin CD11/CD18 on the PMN surface recognizing the counterligand ICAM1 on the endothelial surface. In the lungs, however, both CD18-dependent and CD18-independent mechanisms exist, and the signals that determine the dependence on CD18 are not clear.¹⁴⁴ For example, PMN migration into the lungs in response to *E. coli* and *P. aeruginosa* is CD18 dependent, whereas PMN migration in response to *S. pneumoniae* does not require CD18. TNF- α and IL-1 β appear to direct CD18-dependent migration, whereas IFN- γ is more important for CD18-independent migration.

Under normal circumstances, PMN migration from the blood into the air spaces is not associated with injury to the endothelial or epithelial barriers. At the endothelial barrier, endothelial cells undergo reversible contraction in response to thrombin and other inflammatory stimuli, thereby opening endothelial junctions and allowing the passage of leukocytes. The alveolar barrier is much tighter, and yet PMNs reach the air spaces with only minor and transient changes in epithelial permeability.^{145,146} During migration the spherical PMNs in the bloodstream change shape, and small specific granules fuse with the leading edge of the cell membrane, providing new membrane material bearing

specific adhesion molecules. PMNs in the air spaces are polarized, which is an initial sign of activation, but contain the full complement of primary azurophilic granules containing myeloperoxidase and defensins.¹⁴⁵ Metabolic studies of PMNs in rabbits with pneumococcal pneumonia and humans with bronchiectasis have shown that most PMNs become activated in the air spaces and not during migration into the lung.^{147,148} However, when endothelial activation is intense or when PMN activation signals are present within the circulation, PMNs become preactivated and migration can be associated with damage to the endothelial and epithelial barriers, with the development of increased-permeability pulmonary edema.¹⁴⁹

Once in the air spaces, PMNs ingest bacteria and fungi that have been opsonized by complement and immunoglobulins that accumulate in the air spaces at sites of inflammation. PMNs contain a series of effector mechanisms to kill bacteria and fungi, including oxidant production, microbicidal proteins in primary azurophilic granules, and extracellular traps (see Fig. 12-4). As microbes are recognized and the phagosome begins to form, the subunits of a nicotinamide adenine dinucleotide phosphate, reduced form (NADPH) oxidase are assembled in the cell membrane, and the cell undergoes a respiratory burst, in which an electron is transferred to molecular oxygen to form superoxide anion, which is reduced again to form hydrogen peroxide. This happens on the invaginating phagosomal membrane, focusing oxidants on the contents of the developing phagosome. As the phagosome forms, the primary granules fuse with the phagosomal membrane, adding myeloperoxidase and cationic antimicrobial peptides to the phagolysosome. Myeloperoxidase catalyzes the formation of hypochlorous acid from hydrogen peroxide and a halide, typically chloride (Cl⁻) because of its high concentration in the cellular environment. Hypochlorous acid is a highly reactive oxidant that oxidizes methionines, tyrosines, and other amino acids on proteins, killing the microbe.

In addition to their presence in airway surface liquid, the primary azurophilic granules also contain high concentrations of the α -defensins, human neutrophil protein 1, 2, and 3.^{150,151} When defensins are added to the phagolysosomal space, they attach to negatively charged microbial membranes via electrostatic interactions and are thought to form lytic pores in the microbial cell wall. PMN defensins have antimicrobial activity for gram-positive and gram-negative organisms, fungi, and some viruses. Defensins are most active under conditions of low ionic strength and lose activity with increasing concentrations of salt or plasma proteins, which interfere with electrostatic interactions between the cationic defensins and the anionic microbial surface.¹⁵⁰ The loss of defensin activity in higher salt concentrations has been proposed as a contributing factor for the pathogenesis of chronic airway infection in cystic fibrosis.¹⁵² In addition to their antimicrobial activity, defensins participate directly in innate and adaptive immunity, because they stimulate IL-8 production by epithelial cells and modulate the responses of T cells and immature DCs.^{151,153}

When phagocytosis is appropriately regulated, microbes are killed within the protected environment of the PMN phagolysosome. However, at sites of intense inflammation, PMNs release superoxide anion, hydrogen peroxide, and

granular contents directly into the extracellular environment, leading to oxidant formation in the alveolar spaces with oxidation of structural proteins in the alveolar walls and intracellular proteins in leukocytes, and the accumulation of defensins and other granular contents in the alveolar spaces.¹⁵⁴ These extracellular products contribute to indirect tissue injury by PMNs.

In addition to killing intracellular microbes using oxidants, chlorination, and antimicrobial peptides, as a final act, PMNs can project uncoiled nuclear DNA into the surrounding environment to form *neutrophil extracellular traps* (NETs) that ensnare and destroy bacteria.^{155,156} NET formation depends on the initial respiratory burst of the PMN and leads to the death of the PMN in a process that is distinct from apoptosis and necrosis.¹⁵⁷ The PMNs of patients with chronic granulomatous disease, which lack a functional membrane NADPH oxidase, do not form NETs following appropriate stimulation.¹⁵⁷ A variety of proinflammatory stimuli activate NET formation, including LPS and IL-8. C5a triggers NET formation in PMNs after priming with IFNs or GM-CSF. Some microbes, including *S. aureus*, *E. coli*, *P. aeruginosa*, and *M. tuberculosis*, directly stimulate NET formation by PMNs.¹⁵⁸ The extracellular DNA mesh contains cationic proteins embedded in the negatively charged DNA net, including histones, defensins, and cathelicidin, which kill enmeshed bacteria. Similar extracellular traps are produced by eosinophils and mast cells, but unlike PMNs, eosinophils apparently survive NET formation. NET formation thickens secretions at sites of inflammation, creating a viscous pus that contains enmeshed microbes. As might be expected, some bacteria produce extracellular enzymes that degrade DNA NETs, including *Streptococcus pyogenes* (DNase Sda1/2) and *S. pneumoniae* (DNase EndA).^{159,160} The mechanisms by which NETs are cleared from the air spaces during resolution of inflammation are not clear.

PMNs have an important role in signaling the activation of adaptive immunity.¹⁶¹ In rabbits with tuberculous pleurisy, PMNs are the first cells that migrate into the infected pleural space, where they produce chemotactic factors that direct the subsequent wave of monocyte recruitment, which characterizes the full inflammatory reaction to *M. tuberculosis*.¹⁶² PMN granule proteins cathepsin G and azurocidin are chemoattractants for mononuclear cells, which mature into macrophages and DCs at sites of inflammation, and neutrophil-derived CC chemokines recruit DCs.^{163,164} PMNs release limited amounts of TNF- α and IFN- γ , which regulate macrophage, T-cell, and DC activation and maturation; however, the large numbers of PMNs at sites of inflammation can bring the concentrations of these PMN-derived cytokines into biologically relevant ranges. PMNs also produce CXC chemokine ligand 10 (IFN- γ inducible protein-10), which is a chemoattractant for natural killer cells and *type 1 T helper* (Th1) cells.¹⁶⁵

At the same time that PMNs participate in and intensify inflammation in tissue, they also produce signals that control and begin the resolution of inflammation. PMNs, like macrophages and endothelial cells, release the secretory leukocyte protease inhibitor, which inhibits PMN elastase.¹⁶⁶ After migration into tissues, PMNs produce lipoxins from membrane arachidonic acid, which inhibit PMN recruitment, superoxide anion generation, and NF κ B

activation and enhance the uptake of apoptotic PMNs by macrophages.¹⁶⁷ PMN-derived oxidants inactivate proteases and other proteins at sites of inflammation.

PMNs and their products are cleared largely by macrophages during the resolution of inflammation. PMNs die primarily by apoptosis, necrosis, or NET formation. Apoptosis is a highly regulated form of cell death and is mediated by a series of intracellular caspases.^{168,169} Apoptosis is mediated via two major pathways: ligation of membrane death receptors, principally FAS/CD95 and TNFRI (p55), and mitochondrial stress that results in the release of cytochrome *c* into the cytoplasm. PMNs undergoing apoptosis express phosphatidylserine on the outer leaflet of the cell membrane and undergo nuclear chromatin condensation and cell shrinkage. Apoptotic PMNs are recognized by macrophages via the class B SR, CD36, and are rapidly ingested, so that large numbers of apoptotic PMNs are usually not seen. Macrophages that ingest apoptotic PMNs produce TGF- β and IL-10, which have anti-inflammatory effects. This process results in the clearance of PMNs and their residual intracellular contents and dampening of inflammation. PMNs that are not ingested by macrophages undergo secondary necrosis with loss of membrane integrity, cytoplasmic swelling, and release of remaining intracellular contents into the inflammatory environment. Intracellular components are recognized as danger signals by macrophages, some of which have been included as “alarmins,” or DAMPs.¹⁷⁰ DAMPs include the nuclear protein high-mobility-group box-1, granular antimicrobial peptides, and other intracellular products. Macrophages that recognize these danger signals produce IL-1 β , TNF- α , IL-8, and other proinflammatory cytokines, initiating or perpetuating inflammatory responses. Some PMNs recovered from the lungs of patients with acute respiratory distress syndrome have features of apoptosis, with small cytoplasmic features and nuclear pyknosis, whereas many have features of necrosis, including severe degranulation, membrane blebbing, and cytoplasmic swelling. The signals that govern the balance between necrosis and apoptosis are incompletely understood.

Thus PMNs are important effector cells in innate immunity, ideally designed to circulate through the body and accumulate rapidly at tissue sites of acute inflammation. Under normal circumstances, they arrive in tissue ready to ingest and kill microbes, then quietly go away by programmed cell death. PMN-derived signals regulate local inflammation and stimulate adaptive immune responses, providing a broader role for PMNs in host defense.

MONONUCLEAR PHAGOCYTES

The concept of the mononuclear phagocyte system as a functionally and phenotypically heterogeneous system of mononuclear phagocytes distributed throughout the body was developed in the 1960s and 1970s through a series of insightful studies pioneered by van Furth and Cohn¹⁷¹ and Volkman and Gowans.¹⁷² The central concept was that the resident macrophages of all organs and tissues were derived from progenitor cells in the bone marrow. In turn, the progenitor cells gave rise to circulating blood monocytes that were recruited into organs and tissues, where they differentiated into macrophages, to maintain

macrophage homeostasis. In response to additional needs during inflammation or infection, monocyte production in the bone marrow increases, thereby enabling increased monocyte recruitment to affected tissues. Although many aspects of this conceptual framework have been confirmed, recent studies building on earlier foundational work¹⁷³⁻¹⁷⁵ have challenged the concept that resident macrophages are derived from bone marrow–derived monocytes and have provided important insights into the origins of resident tissue macrophages during early embryonic development.^{176-185,185a} Fate-mapping studies involving lineage-tagged mice and other genetic models have suggested that there is a pool of “primitive” F4/80 bright resident macrophages located within tissues that are derived from the yolk sac beginning on *embryonic day 8* (E8) (Fig. 12-5A).^{177,181,186} In addition to expressing high levels of F4/80, these yolk sac–derived macrophages express CX3CR1, *macrophage mannose receptor* (MMR), and colony-stimulating factor 1 receptor (CSF1R, *c-fms*) and are dependent upon IL-34, CSF1, and the transcription factor PU.1

for their development (see Fig. 12-5A).^{181,187-190} By E10.5, yolk sac–derived macrophages are found in most tissues, including the lung, and are able to undergo self-renewal.^{173,175,181,184,191} At E10.5 the fetal liver becomes the major site of hematopoiesis,¹⁹² and with its development, a unique “definitive” macrophage population derived from the hematopoietic stem cell can also be found.^{181,189} These cells express low levels of F4/80, high levels of CD11b, and, in contrast to the yolk sac–derived macrophages, are dependent on the transcription factor c-Myb for development.¹⁸¹ During liver hematopoiesis, macrophages constitute up to 15% of the total cells in many organs,¹⁸⁹ and their importance in embryonic development has been definitively shown in studies using *c-fms*-, colony-stimulating factor 1-, CX3CR1-, c-Myb- and PU.1-deficient mice.¹⁷⁸⁻¹⁸² These studies also showed that adult Langerhans cells, the prominent antigen-presenting cells of the skin, are produced by the fetal liver and that their development is dependent on IL-34 and CSF1R. In studies using these and other models, macrophages have been shown to play important roles in

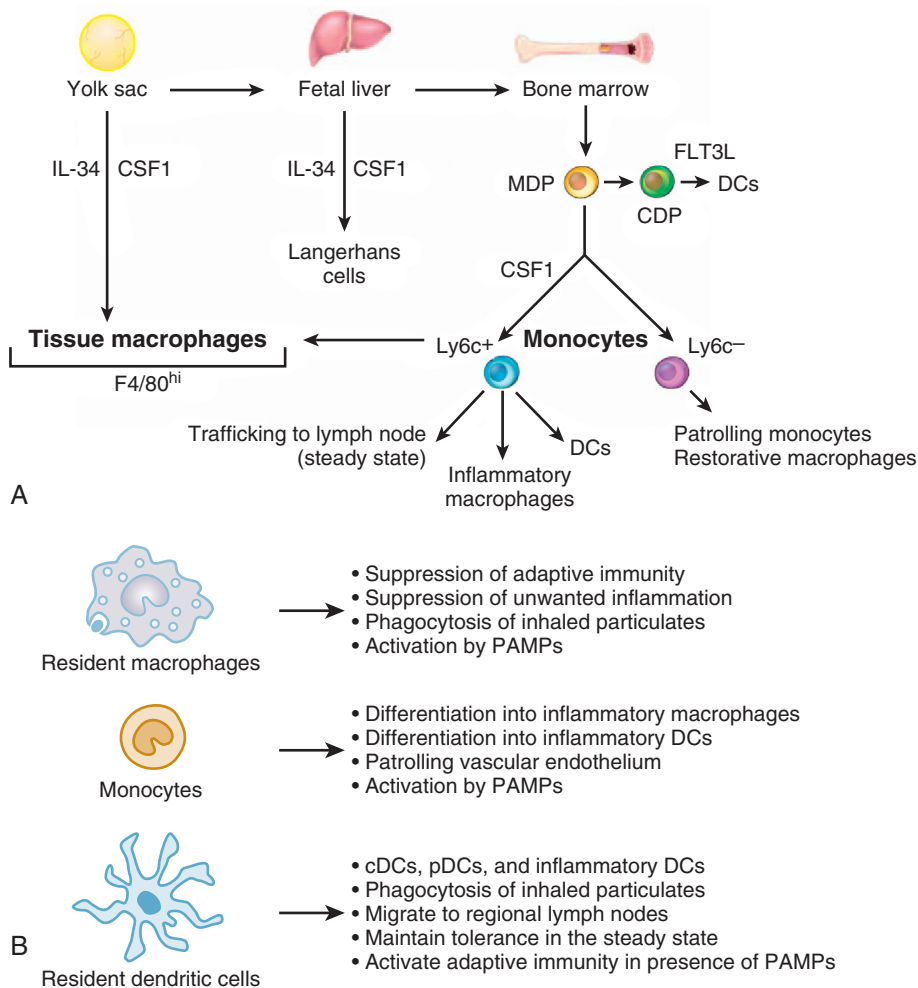

Figure 12-5 Pathways of development of resident tissue macrophages and blood monocytes. **A**, Monocytes can traffic to lymph nodes, develop into inflammatory and restorative macrophages and dendritic cells (DCs), or be maintained as patrolling cells in the circulation in mice. **B**, In the steady state, lung mononuclear phagocytes can be considered to include (1) resident macrophages of the alveoli and alveolar septae, (2) marginating monocytes of the lung microvasculature, and (3) resident dendritic cells. Each of these subsets exhibits overlapping and unique functions. cDC, conventional DC; CDP, common DC precursor cell; CSF1, colony-stimulating factor 1; FLT3L, FLT3 ligand; IL, interleukin; MDP, macrophage and DC precursor; PAMP, pathogen-associated molecular pattern; pDC, plasmacytoid DC. (A, Adapted and redrawn from Wynn TA, Chawla A, Pollard JW: Macrophage biology in development, homeostasis and disease. *Nature* 496:445–455, 2013.)

bone morphogenesis, ductal branching in the mammary gland, neuronal patterning, angiogenesis, vascular remodeling, and in kidney and endocrine development.^{180,193,194} Analysis of embryonic tissue for yolk sac–derived and hematopoietically derived macrophage populations has shown that the lungs basally contain macrophages of both yolk sac and hematopoietic stem cell origin.¹⁸¹ However, a more detailed analysis of the precise location of these subpopulations (e.g., airway or interstitium), their unique cell surface marker profiles, and how they interact with other pulmonary cells during development has yet to be conducted. Macrophages may contribute to lung development through the clearance of cellular debris associated with tissue remodeling¹⁹⁵ and through the production of growth factors that influence the airway epithelium.^{190,196} Recently, colony-stimulating factor 1 receptor–positive macrophages with a “remodeling” phenotype have been shown to be located near branch points in the lung during branching morphogenesis,¹⁹⁷ though the origin and location of these cells within the adult lung remains unknown.

In addition to macrophages, DCs play a fundamental role in lung innate immunity. Steinman¹⁹⁸ published the first report on a population of antigen-presenting cells in mouse spleen and, based on their morphologic characteristics, coined the name *dendritic cells* (DCs). This work was recognized in 2012 with the posthumous award of the Nobel Prize in Physiology or Medicine. Since the late 1980s a vast array of monoclonal antibodies against monocytes, macrophages, and DC cell surface antigens, together with lineage-tracing mice, have been developed and used to classify monocytes/macrophages and DCs.¹⁹⁹ The issue of using cell surface markers to separate macrophages and DCs is particularly relevant in the lung, where CD11c is expressed at high levels on resident alveolar macrophages, and DCs (as reviewed by Hume²⁰⁰). In addition, much of our initial understanding of the functions of resident lung mononuclear phagocytes has come from studies conducted without the use of extensive cell surface marker panels or lineage-tracing technologies. Thus, although it is clear that the cells described in many studies are mononuclear phagocytes, it is sometimes difficult to classify them further without the use of multiple antibody markers combinations.²⁰¹ As illustrated in [Figure 12-5B](#), pulmonary mononuclear phagocytes can be broadly thought of as three overlapping subpopulations: (1) resident macrophages of the alveolar surfaces and interstitium, (2) monocytes that marginate in the lung microvasculature and can be recruited into the air spaces in response to innate activation, and (3) resident and recruited DCs of the airways and lung parenchyma. In this section, we discuss the localization and innate immune functions of each group of cells.

Resident Macrophages

Resident alveolar macrophages reside in the mixed environment of epithelial lining fluid and ambient inhaled air, whereas resident interstitial macrophages are located within the interstitial tissue or alveolar septa. Morphometric analyses indicate that the number of interstitial macrophages in normal lung is between one tenth and one half of the total number of alveolar macrophages.²⁰²⁻²⁰⁴ Unlike resident alveolar macrophages that can be obtained by bronchoalveolar lavage, interstitial macrophages can be

obtained only by using tissue dispersion techniques. Consequently, considerably less is known about the biology and function of interstitial macrophages than about resident alveolar macrophages, especially in humans. In addition, interpreting current and past studies can be difficult because artifacts in cell phenotype and function can be introduced as a consequence of the tissue dispersion approach or by in vitro exposure to trace amounts of contaminating PAMPs during isolation. Despite these caveats, interstitial macrophages are thought to share many functional similarities with resident alveolar macrophages.

Functions of Resident and Interstitial Alveolar Macrophages

The primary functions of resident alveolar macrophages are (1) to dispose of inhaled microbes and particulates, (2) to clear pulmonary surfactant, and (3) to suppress the development of inappropriate inflammatory and immune responses. Resident alveolar macrophages are capable of phagocytosing a wide spectrum of harmless and harmful microbes and other particulates. Under basal conditions, most ingested phagocytosed particulates are enclosed within phagosomes, which ultimately fuse with lysosomes, leading to their degradation by an array of acid-pH optimum hydrolytic enzymes. Some inhaled microbes (e.g., *M. tuberculosis*) and some environmental particulates (e.g., crystalline silica) are resistant to this process and become sequestered in secondary lysosomes where they remain for the life span of the macrophage. Most of these latter cells probably crawl into the airways and are cleared via the mucociliary escalator.^{205,206} Some particle-laden macrophages may remain in the lung for extended periods of time before either dying and releasing their particle burden, thereby rendering it available for phagocytosis by other macrophages, or undergoing apoptosis and being cleared by other phagocytes.

Resident alveolar macrophages also actively contribute to the normal homeostasis of pulmonary surfactant. This point is most clearly emphasized in patients with pulmonary alveolar proteinosis, a disorder characterized by the accumulation of proteinaceous and lipid-rich surfactant in the alveoli, leading to impaired gas exchange. A fundamental characteristic of the disorder is the finding that alveolar macrophage numbers are reduced, and those that are present are inefficient in clearing pulmonary surfactant.^{207,208} Several studies have shown that pulmonary alveolar proteinosis is associated with the development of autoantibodies against GM-CSF,²⁰⁷⁻²⁰⁹ emphasizing the importance of GM-CSF in the activities of resident alveolar macrophages. Additional information about alveolar proteinosis can be found in Chapter 70.

Lastly, resident alveolar macrophages play a critically important role in tonic suppression of alveolar inflammation and adaptive immunity. Based in part on studies by Maclean and associates,²¹⁰ the concept has evolved that the lung can deal with inhaled microbes and particulates until a certain threshold burden is reached. The threshold is in part determined by the phagocytic capacity of alveolar macrophages. Once the threshold is exceeded, microbes and other particulates are phagocytosed by resident DCs that “snorkel” through tight junctions of the alveolar epithelium to sample the alveolar compartment. Consistent with this concept, studies have shown that depletion of alveolar

macrophages with liposome-encapsulated clodronate augments antigen presentation by pulmonary DCs, which in turn augments adaptive immune responses to intratracheal antigens.^{211,212} Other studies have shown that resident alveolar macrophages suppress the functions of natural killer cells and plasma cells.^{85,213}

The ability of resident alveolar macrophages to suppress inflammation and T-cell responses is specific to these cells and is not a characteristic of macrophages obtained from other locations or peripheral blood.^{214,215} These findings suggest that the alveolar microenvironment may play an important role in the development of suppressive activity by resident alveolar macrophages. As noted earlier, the pulmonary collectins SP-A and SP-D inhibit PAMP-dependent production of proinflammatory cytokines through their interaction with signal-inhibitory regulatory protein α .¹⁹ In addition, TGF- β , produced by alveolar macrophages and activated at the surface of alveolar epithelial cells by the integrin $\alpha\beta$ 6, has been shown to basally suppress alveolar inflammation.^{216,217} Other studies have emphasized the importance of IL-10, prostaglandin E₂, and nitric oxide in the tonic suppression of alveolar inflammation and adaptive immunity.^{218,219} Together these studies suggest that resident alveolar macrophages have several mechanisms that actively suppress alveolar inflammation and the antigen-presenting activity of interstitial DCs, while remaining poised to reverse this response upon appropriate stimulation.

The tonic suppressive activity of alveolar macrophages can be reversed in two different ways. One mechanism involves exceeding the threshold phagocytic capacity of resident alveolar macrophages, thereby allowing microbes to interact with other lung cells, for example, pulmonary DCs or epithelial cells, which respond to PAMPs and other molecules by producing proinflammatory cytokines. Indeed, GM-CSF and TNF- α have been shown to reverse tonic suppression of adaptive immunity in vivo.²²⁰ A second mechanism involves alveolar macrophages themselves. Here, PAMP recognition by the globular head groups of SP-A and SP-D enables lung collectins to interact with macrophages via calreticulin and CD91.¹⁹ In contrast to the suppressive signal initiated when SP-A and SP-D interact with macrophages via signal-inhibitory regulatory protein α in the absence of PAMPs, CD91 signaling leads to the production of proinflammatory cytokines, which then augment inflammation and the recruitment of PMNs and monocytes. Thus resident alveolar macrophages are capable of suppressing inappropriate alveolar inflammation and adaptive immune responses to commonly encountered antigens. However, mechanisms exist to overcome this suppression to allow the recruitment of inflammatory cells, especially PMNs and monocytes, and to promote adaptive immunity.

Recruitment of Mononuclear Phagocytes

After birth and postnatal bone formation, liver hematopoiesis declines and is replaced by bone marrow hematopoiesis, which then becomes the exclusive source of circulating monocytes. Circulating monocytes have the potential to differentiate into macrophages or DCs,²²¹⁻²²⁶ and until recently it was thought that circulating monocytes contribute to the replenishment of resident lung macrophages.²²⁷⁻²²⁹ However, recent incisive studies have clarified the extent

and circumstances under which monocytes replenish resident macrophage and DC populations. In 1989 Passlick and associates reported heterogeneity among human macrophages based on the differential expression of CD14 and CD16.²³⁰ “Classic” CD14^{hi}CD16⁻ monocytes make up approximately 95% of circulating monocytes in the steady state, and “nonclassic” CD14^{lo}CD16⁺ monocytes constitute the remaining 5%.^{231,232} Similar to human monocytes, mouse monocytes have also been classified into classic (Ly6C^{hi}(GR1⁺)CCR2⁺CX₃CR1^{lo}) and nonclassic (Ly6C^{lo}(GR1^{lo})CCR2^{lo}CX₃CR1^{hi}) monocyte subsets.^{185a,225,233,234} During steady-state conditions Ly6C^{lo} monocytes circulate through tissues and patrol the lung microvasculature (see Fig. 12-5A). This subset also expresses high levels of fractalkine receptor (CX₃CR1), which interacts with fractalkine (CX₃CR1L) expressed on the luminal face of vascular endothelial cells and promotes heterotypic adherence.^{233,235} The Ly6C^{hi} monocyte population transmigrates into tissue under inflammatory and injury conditions in a CCR2-CCL2 (macrophage chemotactic protein 1)-dependent manner and differentiates into inflammatory macrophages and dendritic cells (see Fig. 12-5A).^{184,226,233,236} Ly6C^{hi} monocytes have also been recognized to be a short-lived obligatory precursor intermediate for Ly6C^{lo} monocytes under steady-state conditions.¹⁸⁴ Jakubzick and colleagues²³⁷ recently provided additional insights by showing that, under steady-state conditions, circulating Ly6C^{hi} monocytes can also constitutively traffic into the lung and lymph nodes without differentiating into resident macrophages or dendritic cells. Rather, these Ly6C^{hi} monocytes acquire antigen and traffic to regional lymph nodes (see Fig. 12-5A).²³⁷ Additional information about the mechanisms of monocyte, macrophage, and dendritic cell migration can be found in Bromley and associates²³⁸ and Springer and colleagues.²³⁹

Functions of Recruited Monocytes and Macrophages.

In contrast to resident alveolar macrophages, recruited monocytes and macrophages have important proinflammatory and host-defense activities including (1) microbial killing and (2) amplification of inflammation. Monocytes and macrophages kill microbes with reactive oxygen species and reactive nitrogen species. *Superoxide anion* (O₂⁻) is mainly produced by the phagocyte NADPH oxidase.²⁴⁰ Like PMNs, monocytes subsequently convert O₂⁻ into additional reactive oxygen species in a myeloperoxidase-dependent fashion,²⁴¹ but as they differentiate into macrophages, intracellular myeloperoxidase content declines and additional reactive oxygen species (e.g., hydroxyl radical [OH⁻]) are formed by the Fenton reaction.²⁴²

The generation of reactive oxygen species is critical to host defense against commonly encountered and pathogenic bacteria. Patients with chronic granulomatous disease and mice bearing a targeted disruption of the p47^{phox} component of the NADPH oxidase^{243,244} are deficient in their ability to control pulmonary and other infections.²⁴³⁻²⁴⁶ However, inappropriate production of reactive oxygen species by macrophages (and other inflammatory cells) can result in epithelial injury that can lead to fibroproliferation, as can be seen with survivors of acute respiratory distress syndrome and patients with idiopathic pulmonary fibrosis, asbestosis, or silicosis.²⁴⁷⁻²⁵⁰ Thus, whereas reactive oxygen

species play a vital role in the protection of the lung against microbes, inappropriate production in response to nonmicrobial particulates and pollutants, including cigarette smoke,²⁵⁰ can result in a spectrum of injury to the airway and alveolar epithelium. Nitric oxide (NO) produced by inducible nitric oxide synthase (iNOS or NOS2) also contributes to macrophage-mediated microbial killing and epithelial injury following condensation with O₂[•] to form peroxynitrite.^{251,252} Whereas the importance of NO in microbial killing of *L. monocytogenes* and *M. tuberculosis* has been clearly demonstrated in mice,²⁵³ the role of NO in host defense in humans is less clear.

Recruited monocytes and macrophages also amplify inflammation through the production of cytokines, chemokines, and lipid mediators. Studies conducted in the late 1970s indicated that macrophages hydrolyze arachidonyl-containing phospholipids in response to exposure to a variety of TLR agonists through the actions of cellular and secreted phospholipase A₂ enzymes.^{254,255} The hydrolysis of arachidonyl-containing phospholipids by phospholipase A₂ enzymes results in the formation of (1) lysophosphatidylcholine, which, upon acetylation, leads to the production of platelet-activating factor²⁵⁶ and (2) arachidonic acid, which serves as a substrate for the production of all eicosanoids (as reviewed by Riches and coworkers).²⁵⁷

Platelet-activating factor is produced within minutes of exposure of macrophages to TLR agonists and has broad proinflammatory activities that promote PMN recruitment, bronchoconstriction, and vasodilation. Platelet-activating factor also primes PMNs, monocytes, and macrophages for enhanced production of proinflammatory cytokines in response to PAMPs.^{258,259} Arachidonic acid is oxidized to prostaglandin E₂, prostaglandin D₂, prostaglandin I₂, and thromboxane A₂ by cyclooxygenase-1 and cyclooxygenase-2, and these prostaglandins have important roles in the regulation of vascular tone and in the feedback inhibition of macrophage effector functions.²⁶⁰ The principal leukotriene produced by macrophages is leukotriene B₄, which is synthesized following TLR engagement and represents the major immediate PMN chemotactic factor produced in the lung before chemokine expression.^{138,261}

Whereas the production of lipid mediators contributes to aspects of early lung inflammation, the production of cytokines and chemokines by macrophages and epithelial cells is necessary for the optimal recruitment of inflammatory cells and for their activation. As discussed earlier, the human chemokine family consists of four closely related subfamilies that have been classified on the basis of the presence and pattern of conserved cysteine residues and have been designated C, CC, CXC, and CXXC families (as reviewed by Kunkel and coworkers²⁶² and Keane and Strieter²⁶³). The CXC and CC families are critical to the development of pulmonary inflammation. Members of the CXC family containing the Glu-Leu-Arg motif stimulate PMN chemotaxis, whereas family members that lack the Glu-Leu-Arg motif (e.g., CXC chemokine ligand 10) are produced in response to IFN- γ and help regulate angiogenic responses.^{264,265} In contrast, CC family members are involved primarily in the recruitment and activation of mononuclear cells. Macrophages are capable of producing CXC chemokines, especially IL-8, in the settings of acute and chronic lung inflammation in patients with bacterial

pneumonia, acute respiratory distress syndrome, idiopathic pulmonary fibrosis, bronchiolitis obliterans with organizing pneumonia, and cystic fibrosis.²⁶⁶⁻²⁶⁹ In addition, CC chemokines, such as macrophage inflammatory protein 1 α , are produced by macrophages in interstitial lung diseases.^{270,271}

Recruited monocytes that develop into macrophages are also capable of further differentiation. Based on earlier work in which different PAMPs were found to induce distinct patterns of macrophage gene expression,^{29,272-274} the concept evolved that different patterns of gene expression could be induced in response to the conditions or stimuli that prevail at the sites to which macrophages have been recruited.²⁷⁵⁻²⁷⁷ For example, exposure of macrophages to Th1 cytokines and TLR ligands (e.g., LPS and polyribonucleic:polyribocytidylic acid) results in increased expression of nitric oxide synthase 2 (NOS2), TNF- α , IL-12, IL-23, and IL-1- β , whereas IL-10 and arginase I expression are repressed. This response generally leads to a “classically activated macrophage” (Fig. 12-6A).^{29,272-274,276,278} In contrast, exposure to Th2 cytokines, including IL-4 and IL-13, leads to a different pattern of gene expression characterized by increased expression of arginase I, FIZZ (found in inflammatory zone), and CC chemokine ligand 19 together with reduced expression of NOS2 in an overall response that leads to an “alternatively activated macrophage” (see Fig. 12-6A).²⁷⁶⁻²⁷⁹ The spectrum of cytokines identified as being capable of inducing alternative macrophage programming is growing and now includes IL-33, IL-21, IL-10, colony-stimulation factors, CXC chemokine ligand 2, CXCL4, glucocorticoids, and TGF- β .²⁸⁰ In addition, a so-called restorative macrophage programming state that is distinct from classically and alternatively programmed macrophages has recently been identified in self-resolving liver fibrosis (see Fig. 12-6A).²⁸¹

Defining these responses as distinct “phenotypes” can be useful in thinking about how macrophages participate in innate immunity and effector cells in the adaptive immune response (see Fig. 12-6A). However, macrophage programming is more complex than some of the simplistic schemes that have been proposed because there are often overlapping patterns of gene expression in response to multiple stimuli.²⁸² Thus it may be more appropriate to think about these adaptive responses as points on a continuum where the response generated is purely an adaptation to the microenvironment that macrophages encounter.^{275,277,283,284} As further evidence of the diversity of macrophage function, differences between gene-expression profiles are also dependent upon genetic background.²⁸⁵ In addition, ligation of distinct receptors and signal transduction pathways leads to differential activation of the transcriptional factors PU.1, STAT1, STAT6, interferon regulatory factors (IRF4, IRF5), PPAR- γ , cyclic 3',5'-adenosine monophosphate (cAMP) responsive element-binding proteins (CREBs), NF κ B, and activator protein-1, which in turn contribute to diversity in macrophage programming (see Fig. 12-6B).²⁸⁶ Macrophage programming is also regulated and enhanced posttranscriptionally by micro-RNAs.²⁸⁷⁻²⁸⁹ Thus diversity in PAMP and stimulus-induced patterns of gene expression by macrophages contributes greatly to their diverse roles in innate protection of the lungs, lung cancer, repair, fibrosis, and microbial elimination.²⁸⁴

Figure 12-6 Macrophage phenotypes and gene expression. **A**, Macrophages display distinct patterns of gene expression in response to type 1 T helper (Th1) cells and Th2-type cytokines and pathogen-associated molecular patterns (PAMPs). Prototypical states are the “classically activated” and “alternatively activated” macrophages. It is likely that macrophages can exhibit a diverse repertoire of other states, including recently described “restorative” macrophages. **B**, Multiple stimuli, acting through multiple combinations of receptors, signal transduction pathways, and transcription factors, lead to complex patterns of macrophage programming-associated gene expression including the development of classically-activated macrophages and alternatively-activated macrophages. In summary, macrophages play key roles in the maintenance of lung homeostasis through their abilities to suppress unwanted inflammation and immune responses to harmless, commonly encountered inhaled materials. However, they remain constantly poised to respond to harmful inhaled microbes and other substances. Part of this response involves calling in additional support through the recruitment of circulating blood PMNs and monocytes. In turn, recruited monocytes can differentiate into macrophages, which can then express appropriate responses to microenvironmental cues that they sense at the site to which they have been attracted.

Dendritic Cells

DCs represent an important group of phagocytic and antigen-presenting cells that act as a bridge between the innate and the adaptive immune systems. In the lung, DCs have been shown to form an extensive intraepithelial and subepithelial network throughout the respiratory tract (Fig. 12-7). DCs are particularly abundant in the nose, trachea, large airways, and alveolar septae.²⁹⁰⁻²⁹⁸ These cells continuously sample the airway and alveolar lumen by extending and retracting bulbous dendritic projections through the epithelium into the airway and alveolar lumen.^{299,300} After encountering antigens and particulate matter in the airway, DCs then leave the epithelium and traffic into regional lymph nodes, where they deliver stimulatory or tolerogenic signals to naive T cells.^{301,302} DCs traffic constitutively in the steady state, and, as such, lung DCs can be considered transient residents that are continuously replenished by bone marrow–derived precursors in the blood.^{294,303,304}

Newly recruited resident DCs have an immature phenotype characterized by the expression of high levels of MHC class II and low levels of co-stimulatory molecules. These cells serve as the body's primary professional antigen-presenting cells that activate and initiate the clonal expansion of antigen-specific T cells. DCs continually endocytose soluble and particulate materials that enter the respiratory tract. If these materials contain PAMPs, DCs will undergo a maturation program associated with the up-regulation of co-stimulatory molecules (such as CD40, CD80, and CD86), activate the expression of genes for cytokines and growth

factors that promote naive T cell activation, and traffic to the regional lymph node (Fig. 12-8). In the absence of PAMPs, DCs encounter and present self-antigen through their ability to phagocytose apoptotic cells. These DCs do not fully mature but still traffic to lymph nodes, where they express tolerogenic receptors (MHC-peptide antigen complexes) and soluble mediators (IL-10, ICOSL, PDL1) to T-cell receptors on naive T cells generating Treg cells that prevent the development of an immune response against harmless antigen (see Fig. 12-8A). This is also seen following sterile injury. In contrast, when they ingest materials in the presence of PAMPs (from bacteria and viruses), DCs activate a program of maturation associated with the down-regulation of endocytic and phagocytic activities, the up-regulation of antigen-processing machinery, the up-regulation of co-stimulatory molecules, especially CD40, CD80, and CD86,^{295,302,305} and the activation of genes encoding cytokines and growth factors that promote downstream naive T-cell activation and maturation into Th1-effector cells,^{306,307} which recirculate to the original site of PAMP activation to augment the development of adaptive immunity (see Fig. 12-8B). When they encounter allergens, DCs elicit an expansion of Th2-effector cells that produces cytokines, including IL-4, IL-5, and IL-13, resulting in the production of *immunoglobulin E* (IgE) (see Fig. 12-8C). With this general overview of DC function as a background, we now discuss in more detail the function and control of the multiple DC subsets represented in the lung. We focus largely on mouse lung DC subsets, because most of the current knowledge has been developed in this species.

Mouse and Human Lung Dendritic Cell Subsets.

Studies using cell surface markers, particularly CD11c and CD8 α , initially suggested that DCs arose from both myeloid and lymphoid precursors that were thought to give rise to a bewildering array of DC subsets.³⁰⁸ Recent studies in mice, however, suggest that DCs can be grouped into three major subsets, namely *plasmacytoid* DCs (pDCs), *conventional* DCs (cDCs), and *inflammatory* DCs (iDCs) (Fig. 12-9).

pDCs are characterized by the presence of TLRs 7 and 9 and expression of the cell surface marker Siglec-H. They also secrete abundant quantities of type I IFNs in response to TLR ligation by PAMPs. Many TLR7 and TLR9 agonists are viral products, and their ability to stimulate type I IFN secretion by DCs is an important component in the early antiviral response. Typically pDCs are present in low numbers in lung tissues in the steady state but are rapidly recruited into the lung when viral PAMPs are detected. Like other DCs, pDCs can also process antigens, traffic to regional lymph nodes, and participate in antigen presentation to naive T cells. In addition, pDCs can also restrain the activity of conventional DCs, thereby controlling both inflammation and the induction of adaptive immunity.

cDCs are the archetypal antigen-presenting DC and can be subdivided into lymphoid *tissue resident* DCs and *migratory* DCs. As their name implies, lymphoid tissue resident DCs reside in spleen and lymph nodes and respond to antigens delivered by draining afferent lymphatic vessels. Migratory DCs also have classic antigen-presenting functions but transiently reside in the airway epithelium and alveolar septae before migrating to regional draining lymph nodes via afferent lymphatics. Migratory DCs extend their

Figure 12-8 Resident lung dendritic cells are capable of inducing the activation of various CD4⁺ T cells. **A**, CD4⁺ T regulatory cells after exposure to harmless antigens. **B**, Type 1 T helper cells CD4⁺ after exposure to PAMPs from bacteria and viruses. **C**, Th2 CD4⁺ T cells after exposure to allergens. DC, dendritic cell; GM-CSF, granulocyte-macrophage colony-stimulating factor; ICOSL, inducible T-cell co-stimulator ligand; IFN- γ , interferon- γ ; IL, interleukin; MHC, major histocompatibility complex; OX40L, OX40 ligand; PDL1, programmed death-ligand 1; PGE₂, prostaglandin E₂; TGF- β , transforming growth factor- β ; TLR, Toll-like receptors; TNF- β , tumor necrosis factor- β ; TSLP, thymic stromal lymphopoietin. (Redrawn from Vermaelen K, Pauwels R: Pulmonary dendritic cells. *Am J Respir Crit Care Med* 172:530–551, 2005.)

dendritic processes through the airway and alveolar epithelial tight junctions to capture, process, and present inhaled antigens in association with MHC class II molecules. Upon migration to lymph nodes, migratory DCs present MHC-peptide antigen complexes and co-stimulatory molecules to naive T cells.

Inflammatory DCs, in contrast to migratory DCs and pDCs, are absent from lymphoid and peripheral tissues under steady-state conditions. However, in response to local activation of innate immunity, Ly6C^{hi} peripheral blood monocytes home to sites of inflammation and/or infection and differentiate into inflammatory DCs in response to specific cytokines, especially GM-CSF and Flt3 ligand.^{224,230} The functions of inflammatory DCs are similar to those of migratory DCs.

It is now recognized that all DCs and monocytes arise from a single myeloid progenitor cell called the “macrophage and DC precursor.”³⁰⁹ The macrophage and DC precursor differentiates to yield common DC precursor cells and monocytes. The common DC precursor cells can further differentiate into pre-conventional DCs and pDCs, whereas monocytes can give rise to inflammatory DCs or retain their

monocytic-like character in tissues under steady-state conditions.²³⁷ In view of these findings, it has been suggested that the earlier classification of DCs into lymphoid DCs and myeloid DCs be abandoned.³¹⁰

Based on cell surface marker expression, mouse lung contains two major subsets of conventional DCs. All mouse lung DCs express high levels of MHC class II proteins and CD11c, but the two subsets can be differentiated by the presence or absence of CD103 (see Fig. 12-9). They can be further subdivided by the presence or absence of CD11b and/or langerin (see Fig. 12-9). Langerin⁺ DCs, which resemble the langerin⁺ DC cells of the skin, exist together with langerin[−] subsets within the epithelium of the trachea and large airways.^{295,311} The langerin⁺ DC subset also expresses CD103 and low levels of CD11b, whereas the langerin[−] DC subset is CD11b^{hi}CD103[−].³⁰² Additional DC subsets are found within the submucosa of the trachea and large airways. These cells are typically CD103[−]CD11b^{hi}CD11c^{hi} and are efficient antigen-presenting cells. Though less well characterized, DCs of the murine lung parenchyma are generally characterized as being CD11c^{hi}CD11b^{lo}CD103[−]CD205⁺. In addition, information on human DC subsets

Figure 12-9 Three major subsets of dendritic cells (DCs) exist in mouse lung: conventional DCs (cDCs) (both migratory and lymphoid tissue resident), plasmacytoid DCs (pDCs), and inflammatory DCs. Each subset can be defined by the expression of distinct patterns of cell surface antigens recognized by monoclonal antibodies. Mac, macrophage. (Redrawn from Geurts-vanKessel CH, Lambrecht BN: Division of labor between dendritic cell subsets of the lung. *Mucosal Immunol* 1:442–450, 2008.)

is limited, and it is unclear to what extent the marker profiles of mouse DC subsets can be translated to humans. Several excellent reviews on mouse lung DC subsets are available.^{312,313}

Studies of human lung DC subsets are limited by difficulties in the availability of tissue samples and, as is the case for interstitial macrophages, the possibility that methods for isolating DCs from lung tissue samples may activate and/or alter DC surface marker expression, thereby introducing artifacts to the analysis. Human lung DCs are distinguished from resident alveolar macrophages by their expression of MHC class II, especially human leukocyte antigen-DR4. In addition, human resident alveolar macrophages are highly autofluorescent, whereas lung DCs exhibit low autofluorescence.³¹⁴ Human lung DCs can be distinguished from other myeloid and lymphoid cells by the absence of T-cell, B-cell, natural killer cell, monocyte, and granulocyte lineage markers. MHC class II⁺ DCs are found in normal human airway epithelium, lung parenchyma, and visceral pleura,²⁹¹ and a langerin⁺ DC subset is present in bronchioles.³¹⁵ As in the mouse, large numbers of DCs are present in alveolar septae.^{290,293} Five subsets of pulmonary cDCs have been found in human lungs. Demedts and colleagues³¹⁶ identified three DC subsets in normal human lung specimens. These include a CD1a⁺MHCII⁺BDCA-1 (blood dendritic cell antigen-1) cDC subset, another cDC subset that expresses BDCA3⁺ and CD11c⁺, and a pDC subset that expresses BDCA2⁺ and CD123⁺.³¹⁷ A fourth langerin⁺ cDC subset is associated with airway mucosal epithelium. A fifth CD103⁺Langerin⁺CD11b^{lo} subset that expresses tight junction pro-

teins, claudin 1, claudin 7, and zona occludens-2 resides beneath the basal lamina of both human and mouse mucosal epithelium.³¹⁶⁻³¹⁹

Inflammatory DCs arise by recruitment of blood monocytes and differentiation in response to activation of innate immune mechanisms. Inflammatory cDCs initially retain monocyte markers and are characterized as CD11c^{hi}CD11b^{hi}Ly6C^{hi}. Based on their ability to produce TNF- α and NOS2, these cells have also been called Tip-DCs.³²⁰

Functions of Lung Dendritic Cells. Lung DCs have the remarkable ability to change their phenotype upon exposure to PAMPs and other “danger” signals.^{321,322} The maturation of immature lung DCs results in functional changes that “polarize” the DC subset. The term *polarization* is used here to indicate that the antigen-exposed DC subset acquires the ability to skew naive T cells to become Th1 or Th2 (or possibly even Th17 or Treg cells).^{198,323-325} The ability to leave the epithelial barrier and migrate to regional lymph nodes is mediated in part by the expression of matrix metalloproteinase-9; in fact, matrix metalloproteinase-9-deficient mice fail to develop allergic airway inflammation.³²⁶ When immature DCs are activated by chemokines, they also down-regulate inflammatory chemokine pathways and traffic into draining lymph nodes by up-regulating CCR7. The CCR7 ligands, CC chemokine ligand 19 and CC chemokine ligand 21, are expressed on peripheral lymphatic endothelium and lymph node stromal cells. This mechanism serves to guide DCs from nonlymphoid into

lymphoid tissues. The use of chemokines, chemoattractant receptors, selectins, and their ligands tightly regulates the migration of pDC and cDC subsets to, from, and within lung tissue. These various interactions have been reviewed by Springer²³⁹ and Bromley and associates.²³⁸

Within draining regional lymph nodes, mature DCs that arrive from the lung are capable of delivering pathogen-specific signals to naive T cells. The further differentiation of these activated T cells into functional T-cell subsets is driven by specific patterns of DC- and T cell–derived cytokines that induce a fully mature T-cell response. These patterns of cytokines then sustain T-cell activation and downstream T-cell skewing.³²¹ For example, IL-12, IL-13, and IL-27, type I IFNs, and ICAM engagement drives the polarization of naive T cells into the Th1 phenotype. In contrast, CCL2 and OX40 ligand promote Th2 phenotype polarization, whereas IL-10, retinoic acid, and TGF- β promote Treg development. The patterns of T-cell cytokine production that develop after exposure to a pathogen are relatively specific to that pathogen and determine in large part the resultant DC subset–driven T-cell response. This mixture of signaling molecules includes proinflammatory and anti-inflammatory cytokines, reactive oxygen species, chemokines, eicosanoids, heat shock proteins, extracellular matrix proteins, and endogenous molecules such as histamine and prostaglandin E₂ that polarize the T-cell phenotype. However, T-cell polarization is not fixed and can change based on alterations in these signaling patterns, which can arise during the maturation of the host response to a pathogen. Nevertheless, in general, the concept that antigens plus PAMPs polarize lung DCs toward antigen-specific T-cell immunity, whereas antigens alone polarize lung DCs toward antigen tolerance³²⁷ appears to be correct. A major benefit of the ability of lung DCs to recognize and clear material present in inhaled air is to maintain efficient oxygen exchange in the lung.

In this way the majority of harmless antigenic materials that are encountered while breathing are eliminated and fail to trigger lung inflammation, ensuring that the lung does not mount an inflammatory or immune response that could result in lung damage.³²⁸ However, harmful PAMP-expressing materials will be recognized and promote inflammation and initiate antigen-specific adaptive immunity.

SYSTEM INTEGRATION

The innate and adaptive immune systems have evolved to protect the lungs from harm by environmentally acquired microbes and other inhaled substances, as well as from host-derived harmful stressors such as unwanted inflammation and inappropriate activation of adaptive immunity. A core concept is that innate immune protection in the lungs is not a consequence of individualized responses of individual cells but, rather, represents coordinated responses and collective cooperation between many resident and recruited lung cell types. These coordinated events result in homeostasis of the airways and gas-exchange units, tolerance to harmless inhaled substances and self-antigens, and vigilance to respond to harmful microbes and substances. In addition, innate immune mechanisms assist in the rapid resolution of injury and restoration of lung function.

From the nose to the alveolus, the respiratory epithelium, interdigitating DCs, and resident and recruited macrophages have evolved exquisite, diverse, and overlapping mechanisms to distinguish between the harmful and harmless. In its simplest form, this distinction is achieved by sensing the presence of microbial PAMPs. In the absence of PAMPs, the epithelium remains largely ignorant of inhaled particulates, whereas “snorkeling” DCs continuously sample the airways and alveoli for particles, antigens, and apoptotic cells to phagocytose and to present antigen to lymph node resident naive CD4⁺ and CD8⁺ T cells, thereby maintaining tolerance to harmless commonly encountered antigens and self-antigens. Similarly, resident macrophages phagocytose and dispose of particulates that reach the alveoli, while tonically maintaining an anti-inflammatory and immunosuppressive environment through the production of anti-inflammatory cytokines, especially TGF- β and IL-10, and eicosanoids such as prostaglandin E₂.

Integration of innate functions is dependent on cell-cell communication. In some settings, communication is fostered by proximity: DCs exist as a network within airway epithelium and contact each other through tight junctions, whereas resident alveolar macrophages use integrins to communicate with alveolar epithelial cells. In other settings, cell-cell communication is mediated through the secretion of a vast array of cytokines and lipid mediators, which can act in autocrine or paracrine fashions. Thus different cell lineages can communicate with each other and among themselves. Communication between different cell types also plays an important role in the coordination of innate immunity and in the activation of adaptive immunity. For example, depletion of resident alveolar macrophages reduces tolerance to inhaled antigens and induces alveolitis and lung injury,^{77,212} emphasizing the importance of resident alveolar macrophages for suppressing inflammation. Integration of innate immunity in the lung is also associated with “coordinated burden sharing.” For example, airway goblet cells and submucosal glands produce mucus, whereas ciliated epithelial cells propel mucus and entrapped particulates toward the pharynx. Similar coordinated burden sharing is exhibited by airway epithelial cells, which are poorly phagocytic but are highly capable of sensing PAMPs and calling in PMNs and monocytes, which in turn are highly phagocytic, microbicidal and eliminate an array of microbes. Together these integrated systems have evolved to provide the lungs with maximum protection against harmful microbes while minimizing harmful responses against harmless inhaled substances. The net result is an exquisite system for protecting the delicate and critically important gas-exchanging parenchyma of the lungs from harm.

Key Points

- A primitive host defense system is broadly based on the recognition of repetitive structures on microbes called *pathogen-associated molecular patterns* (PAMPs) by pattern recognition receptors expressed on lung cells.
- Airway epithelium of the trachea and large airways is protected by (1) airway surface liquid, which contains antibacterial proteins, (2) mucus, which traps large

inhaled particulates and transports them to the pharynx by mucociliary transport, and (3) immune cells, which produce chemokines, cytokines, and lipid mediators in response to PAMPs.

- Alveolar epithelium is protected by surfactant proteins A and D, which serve the dual purpose of (1) opsonizing microbes and (2) suppressing unwanted inflammation and adaptive immune responses to commonly encountered antigens.
- Polymorphonuclear leukocytes (i.e., neutrophils) are recruited to the airways and alveoli when airway and alveolar epithelial cells detect PAMPs. Neutrophils phagocytose and kill microbes by combined oxidative and nonoxidative mechanisms.
- Macrophages are resident phagocytic cells of the alveolar lumen that are involved in the removal of a wide range of microbial and nonmicrobial inhaled particulates. Macrophages also suppress unwanted alveolar inflammation and adaptive immunity in the steady state but can be activated by PAMPs to amplify inflammation.
- Dendritic cells are the primary antigen sensing and presenting cells of the innate immune system. In the absence of PAMPs, immature dendritic cells traffic to regional lymph nodes and promote tolerance to inhaled antigens. In the presence of PAMPs, dendritic

cells mature, express co-stimulatory molecules, and promote T-cell development into Th1, Th2, Th17, or Treg effector cells.

- The cell lineages of innate lung immunity collaborate to promote optimal responses to perceived danger signals (primarily PAMPs) while maintaining tolerance to inhaled antigens in the steady state.

INTRODUCTION

The human immune system consists of many different cell types and organs that have evolved to destroy or control potentially harmful foreign substances. The immune response is essential for survival because it constitutes the principal means of defense against infection by pathogenic microorganisms, including those that enter and reside in the respiratory tract. The immune response is also critically involved in pathologic processes of the lung and upper respiratory tract. This chapter provides an understanding of the adaptive (or acquired) immune response, which depends on the specific recognition of antigens by T and B lymphocytes. Immune recognition is highly specific for a particular pathogen, and yet an individual's immune cells can collectively respond to an almost unlimited number of foreign antigens. The molecular mechanisms underlying this specificity and diversity are unique to the immune system. The adaptive immune response also changes after successive encounters with the same pathogen. For example, memory of an antigen allows the immune system to respond faster and in greater magnitude compared with the initial encounter. This chapter also describes how primary and secondary immune responses are regulated by complex cellular interactions and the release of particular types of soluble mediators. Antigen-specific immune responses are also regulated and augmented by nonspecific inflammatory cells of the immune system, such as dendritic cells, macrophages, neutrophils, eosinophils, and mast cells. Defects in the development of adaptive immunity are discussed in Chapter 92 on primary immunodeficiencies.

COMPONENTS OF THE IMMUNE SYSTEM: OVERVIEW

All of the cells of the immune system arise from pluripotent hematopoietic stem cells through two main lines of differentiation that give rise to the lymphoid lineage and the myeloid lineage.¹ Specificity within the immune system is primarily provided by lymphocytes. The two major categories of lymphocytes are T cells,² which are derived from

bone marrow stem cells and primarily develop in the thymus, and B cells, which develop in the bone marrow in adult humans. A third population of lymphocytes is *natural killer* (NK) cells.

Lymphocytes and other cells of the immune system express a large number of different molecules on their surfaces. Some of these markers can be used to separate cells with different functions or to distinguish cells at particular stages of differentiation. Monoclonal antibodies to many different cell surface markers have been produced, and a systematic nomenclature has been developed. The CD ("cluster of differentiation" or "cluster determinant") system provides a basis by which monoclonal antibodies that bind to the same surface molecule are grouped together, and the CD number is used to indicate the specific molecule recognized. Tables 13-1 to 13-3 provide a partial list of surface antigens, particularly those mentioned in this chapter. The markers are partially grouped based on the cell type expressing them. It may be necessary to refer to this list of molecules throughout this chapter.

T cells are distinguished by the presence of the *T-cell receptor* (TCR).³⁻⁵ Most T cells express a receptor composed of an α and a β chain, whereas a much smaller subset expresses a structurally similar receptor composed of a γ and a δ chain. Both receptors are associated with a complex of polypeptides, the CD3 complex, which provides a transmembrane signaling function and allows TCR engagement to be coupled to cellular activation. T cells expressing $\alpha\beta$ TCRs can be divided into CD4⁺ and CD8⁺ T-cell subsets. CD4⁺ T cells primarily recognize antigens presented by *major histocompatibility complex* (MHC) class II molecules. CD8⁺ T cells primarily recognize antigens presented by MHC class I molecules. Functionally, T cells can be divided into several major subsets. For example, T helper cells may interact with B cells and help them to survive and divide, make antibody, and become memory B cells. T helper cells also may interact with cytotoxic T cells or with phagocytic cells and help them destroy intracellular pathogens. Different subsets of T helper cells can be distinguished by the pattern of cytokines that they secrete during an immune response. T helper cells are generally encompassed within the CD4⁺ T cell subset. Another subset of T cells is responsible for destruction of cells that have become infected by virus or

Table 13-1 Selected Cell Surface Markers of Human T Cells

Cell Surface Markers	Identity/Function
TCR	Interacts with peptide/MHC complex on antigen-presenting cells
CD2	Binds to LFA3; involved in co-stimulation and adhesion
CD3	T-cell signaling complex
CD4	T-cell subset with helper function; interacts with MHC class II molecule
CD8	T-cell subset with cytotoxic function; interacts with MHC class I molecule
CD25	α chain of IL-2 receptor; expressed on activated T cells and on a subset of regulatory CD4 ⁺ T cells
CD28	Binds B7-1 (CD80) and B7-2 (CD86); co-stimulatory molecule involved in T-cell activation
CD45	Phosphatase involved in cellular activation and differentiation; different isoforms (CD45RA, CD45RO) mark naive versus previously activated T cells and stages of activation
CD62L	L-selectin; involved in lymphocyte adhesion; levels mark naive versus memory cells
CD69	Activation marker
CD95 (FAS)	FAS; receptor involved in apoptosis
CD95L (FAS ligand)	Ligand for FAS; involved in T-cell-mediated killing
CD152 (CTLA4)	Binds to B7-1 (CD80) and B7-2 (CD86); involved in down-regulation of TCR signaling
CD154 (CD40 ligand)	Ligand for CD40; important for T-cell activation and T-cell-dependent B-cell activation
CD134 (OX40), CD137 (4-1BB), ICOS, PD1	Additional co-stimulatory molecules in the TNF or CD28 family; involved in T-cell activation and regulation

CTLA4, cytotoxic T lymphocyte antigen-4; ICOS, inducible co-stimulator; IL-2, interleukin-2; LFA3, lymphocyte function-associated antigen-3; MHC, major histocompatibility complex; PD1, programmed cell death-1; TCR, T-cell receptor; TNF, tumor necrosis factor.

other intracellular pathogens. These cells are called “cytotoxic T cells” and usually express the CD8 phenotypic marker. Although not clearly distinguished by phenotypic markers, separate subsets of T cells, within both the CD4 and CD8 subsets, have been termed “T regulatory (or suppressor) cells” because they down-regulate immune responses.

B cells are identified by the expression of surface *immunoglobulin* (Ig) or antibody molecules, which represent their specific *B-cell receptor* (BCR) for antigen. Analogous to the CD3 complex on T cells, BCRs are also linked to accessory molecules, Ig- α (CD79a) and Ig- β (CD79b), which are required for cellular activation after antigen interaction.⁶ After differentiation, B cells can develop the ability to produce high levels of antibody (soluble Ig). B cells also express a large number of other surface markers that are critically involved in their function and interaction with T cells. For example, most B cells express MHC class II molecules that allow them to present antigen to T helper cells. Other B-cell surface molecules are listed in [Table 13-2](#).

Table 13-2 Cell Surface Markers of Human B Cells

Cell Surface Markers	Identity/Function
BCR	Immunoglobulin molecules; recognizes antigen
CD5	Binds to CD72; regulation of cell proliferation/activation; identifies B1a cell subset
CD19	B-cell coreceptor subunit; involved in co-stimulation
CD20	B-cell marker
CD21	Complement receptor type II; B-cell coreceptor subunit; marks certain B-cell subsets; EBV receptor
CD22	Adhesion molecule; involved in B-cell activation
CD23	Identifies B-cell subset; low-affinity receptor for IgE
CD40	Binds CD40L; involved in T-cell-dependent B-cell activation
CD79a (Ig- α)	Involved in B-cell activation; signaling through BCR
CD79b (Ig- β)	Involved in B-cell activation; signaling through BCR
CD80 (B7-1)	Binds CD28 and CD152 (CTLA4) on T cells
CD86 (B7-2)	Binds CD28 and CD152 (CTLA4) on T cells

BCR, B-cell receptor; CD40L, CD40 ligand; CTLA4, cytotoxic T lymphocyte antigen-4; EBV, Epstein-Barr virus; Ig, immunoglobulin.

A third population of lymphocytes is probably best defined as those cells that do not express either TCR or Ig and mostly includes NK cells.⁷ A large proportion of this subset contains numerous electron-dense granules and is recognized morphologically as large granular lymphocytes. Markers on these cells are frequently shared with T cells (e.g., CD2 and CD8) or cells of the myelomonocytic series, for example, the integrin molecule CD11b or the low-affinity receptor for IgG (FCGR3 or CD16). NK cells appear to play an important role in the initial (innate) host defense against infection and tumor cells. Similar to certain phagocytes, they also have the capability to destroy target cells or pathogens that have been coated with specific antibody via a process known as antibody-dependent cellular cytotoxicity.

The myeloid lineage consists primarily of monocytes (macrophages) and neutrophils, which provide nonspecific inflammatory mediators and phagocytic function. These cells are critically involved in the nonspecific component of the inflammatory response (see Chapters 12 and 15). In addition, macrophages and certain other nonlymphoid cells, such as dendritic cells, are specialized to present antigens to T cells, thus contributing to specific immune responses.

The cells involved in the immune response are organized into tissues and organs. Primary lymphoid organs are the major sites of lymphopoiesis, in which stem cells and their committed precursor cells differentiate into lymphocytes and acquire specific functions. In humans, T lymphocytes mainly develop in the thymus, and B lymphocytes develop in the fetal liver and adult bone marrow. In the thymus, T-cell differentiation also includes acquiring the ability to recognize foreign antigens in the context of self-MHC molecules and the elimination of self-reactive cells (self-tolerance). B-cell acquisition of self-tolerance during development appears to take place in the bone marrow.

Differentiated lymphocytes migrate to secondary lymphoid organs, which include lymph nodes, spleen, and

Table 13-3 Other Cell Surface Markers of General Interest

Cell Surface Markers	Distribution	Identity/Function
CD1	Thymocytes, subset of lymphocytes, antigen-presenting cells	MHC class I–like molecule; involved in presentation of nonpeptide antigens
CD11a	Leukocytes	α chain of LFA1; associates with CD18; interacts with ICAM1; involved in adhesion and migration
CD11b	NK cells, monocytes, granulocytes	α chain of CR3; adhesion molecule
CD11c	Monocytes, granulocytes	α chain of CR4; adhesion molecule; identifies dendritic cells
CD14	Granulocytes, monocytes	Receptor for LPS/LPB complex; myeloid differentiation antigen; cell activation
CD16	NK cells, monocytes	FCGR3; low-affinity receptor for IgG; involved in ADCC
CD18	Leukocytes	β chain of β_2 integrin molecules, including LFA-1, CR3, and CR4
CD29	Leukocytes	β chain of β_1 integrin molecules, including VLA1-VLA6
CD32	B cells, monocytes, granulocytes	FCGR3
CD35	B cells, subset of NK cells, monocytes, granulocytes	CR1
CD45	Leukocytes	Leukocyte common antigen; phosphatase; involved in cell signaling
CD46	Broad distribution	Membrane cofactor protein; regulates complement activation
CD54 (ICAM1)	Broad distribution	Binds LFA1; adhesion molecule
CD56	NK cells	Neural cell adhesion molecule
CD58 (LFA3)	Broad distribution	Binds CD2; adhesion molecule; involved in cell signaling

ADCC, antibody-dependent cellular cytotoxicity; CR, complement receptor; ICAM1, intercellular adhesion molecule-1; IgG, immunoglobulin G; LFA, leukocyte function–associated antigen; LPB, LPB binding protein; LPS, lipopolysaccharide; MHC, major histocompatibility complex; NK, natural killer; VLA, vascular leukocyte adhesion molecule.

mucosa-associated lymphoid tissues, such as the tonsils, lymph nodes of the respiratory tract, and Peyer patches of the gut. These tissues provide an environment for lymphocytes to interact with each other, with antigen-presenting cells and other accessory cells, and with foreign antigens. The immune response is generated mostly within these secondary lymphoid organs, and lymphocytes migrate through the blood and lymph from one lymphoid organ to another and to nonlymphoid tissues. For example, foreign antigen exposure in the lung usually involves the movement of antigen to surrounding lymph nodes, where the specific immune response by T and B cells takes place. Generation of a cell-mediated immune response or antibody response allows antigen-specific effector T cells or specific antibodies, respectively, to travel back to lung tissue for a direct assault on foreign antigens.

Under normal conditions, there is a continuous active flow of lymphocyte traffic through the lymph nodes. About 1% to 2% of the lymphocyte pool recirculates each hour, allowing a large number of antigen-specific lymphocytes to come into contact with their appropriate antigen. Recirculating lymphocytes leave the blood and enter the lymph node through specialized postcapillary venules, known as *high endothelial venules* (HEVs). Specific interacting receptors on lymphocytes and HEV cells facilitate this homing process. Lymphocytes return to the circulation by way of afferent lymphatics that pass via the thoracic duct into the left subclavian vein. Lymphocytes also enter mucosa-associated lymphoid tissues, such as the tonsils and Peyer patches, via HEVs. The recirculation and trafficking of memory and effector T and B cells is tightly regulated, determined by unique combinations of adhesion molecules and chemokines.⁸ For example, certain lymphocytes may preferentially migrate across HEVs into intestinal lymphoid tissues (either Peyer patches or mesenteric lymph nodes) or

into respiratory tract tissues or may specifically home to the peripheral lymph nodes or the spleen.

Separate combinations of cell-surface adhesion molecules and chemokines allow activated lymphocytes and other leukocytes to migrate into nonlymphoid tissues, especially during inflammation and in response to the release of inflammatory cytokines.⁸ The difference in trafficking patterns for nonactivated (resting) versus activated lymphocytes is striking and emphasizes the importance of particular adhesion molecules in the control of lymphocyte migration.

IMMUNE RECOGNITION

B CELLS AND ANTIBODIES

Structure of Immunoglobulin and the B-Cell Receptor for Antigen

Immunoglobulin molecules, or antibodies, are glycoproteins that act as BCRs. These molecules can also be secreted in large quantities by activated B cells and plasma cells. [Figure 13-1](#) shows the basic structure of an Ig molecule. Each Ig molecule is bifunctional—one region (Fab) binds to antigen, and a different region (Fc) mediates various effector functions, such as binding to host tissues (via their cell surface Fc receptors) and binding to and activating the first component of the classic complement system.

The basic structure of all Ig molecules involves two identical light polypeptide chains and two identical heavy polypeptide chains linked together by disulfide bonds (see [Fig. 13-1A](#)). The isotype (class or subclass) of an Ig molecule is determined by its heavy chain type. There are five Ig classes—IgG, IgM, IgA, IgD, and IgE—corresponding to the

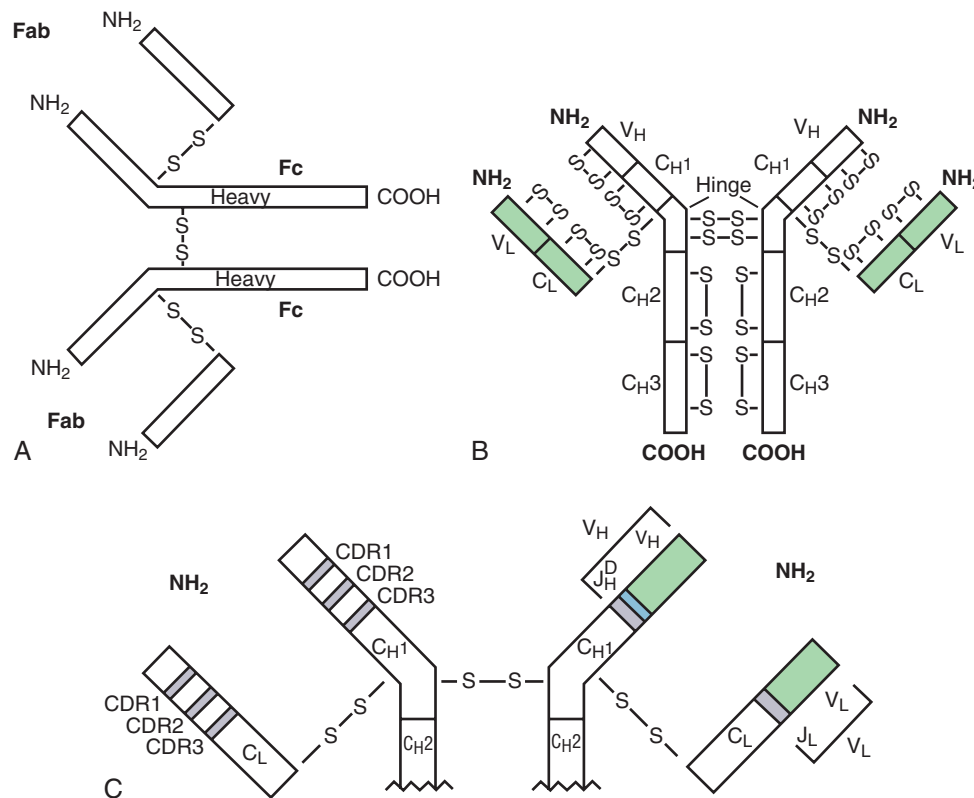

Figure 13-1 The structure of immunoglobulin molecules. **A**, Basic immunoglobulin (Ig) structure with two heavy chains and two light chains linked together by disulfide bonds. The Fab region is involved in antigen binding, whereas the Fc region mediates various effector functions. **B**, Increasing detail of IgG molecule showing domains of both heavy and light chains. Each domain has an internal disulfide bond. The sites of antigen binding involve the NH₂-terminal domains of both the heavy and the light chains and are referred to as the “variable regions” (V_H and V_L, respectively). The rest of each chain has a relatively constant structure (C_H and C_L domains). **C**, Close-up of the antigen-binding variable regions. On the left, the complementarity-determining regions (CDRs) are shaded because they are the most variable components and are most involved in actual antigen binding. The CDRs are separated by intervening segments referred to as “framework regions.” On the right, the Ig polypeptide regions are correlated with the Ig gene segment (exons) that encode the variable region. Note that CDR3 corresponds to the V_H/D_H/J_H junctional region of the rearranged heavy chain gene and the V_L/J_L junctional region of the rearranged light chain gene. (Adapted from *MKSAP in the specialty of rheumatology*, Philadelphia, 1993, American College of Physicians, p 6.)

γ , μ , α , δ , and ϵ heavy chain types. In humans, there are four IgG subclasses, IgG1 to IgG4. There are major differences in the structure and main functions of these different Ig classes and subtypes.

In [Figure 13-1B](#), the IgG molecule is shown as an example of basic antibody structure. Each chain is composed of a series of globular regions or domains. Each domain encompasses about 60 to 70 amino acids and has an internal disulfide bond. The site of antigen binding is the amino (NH₂)-terminal domain for both the *heavy* (H) and *light* (L) chains. This domain is characterized by remarkable sequence variability and is referred to as the “variable region” of the heavy and light chains (V_H and V_L region, respectively). The combination of V_H and V_L forms the antigen-binding site, and there are two such sites per IgG molecule (see [Fig. 13-1B](#)). The rest of each polypeptide has a relatively constant structure. The constant domain of the light chain is termed the “C_L region,” whereas the heavy chain has three constant domains: C_H1, C_H2, and C_H3. The hinge region, located between the C_H1 and C_H2 domains, provides flexibility and independence to the two antigen-binding sites. In both μ and ϵ heavy chains, there is an additional constant domain between C_H1 and C_H2, resulting in a total of four constant domains.

The greatest variability in antibody molecules takes place in the V_H and V_L domains, and these domains are responsible for the specificity in antigen binding.^{9,10} Within the variable domains (see [Fig. 13-1C](#)), certain short segments show exceptional variability and are called “hyper-variable regions.” These regions are also referred to as *complementarity-determining regions* (CDRs) because they are directly involved in the binding to antigen. In both the V_H and V_L regions, there are three CDRs (CDR1 to CDR3) with intervening segments referred to as “framework regions” (see [Fig. 13-1C](#)). CDR3 (a component of the polypeptide V region) is formed by parts of the V (variable), D (diversity), and J (joining) gene segments. Variation within the V_H and V_L regions distinguishes one antibody molecule from another and is referred to as “idiotypic” or “idiotypic variation.” Additional information on heavy chain rearrangement is shown in [eFig. 13-1](#).

Formation of the B-Cell Receptor Repertoire

The BCR repertoire and the Ig molecules are characterized by enormous diversity. The principal genetic mechanisms that are used to generate this diversity include (1) genetic recombination of gene segments to form a functional Ig gene, (2) combinatorial diversity of heavy and light chain

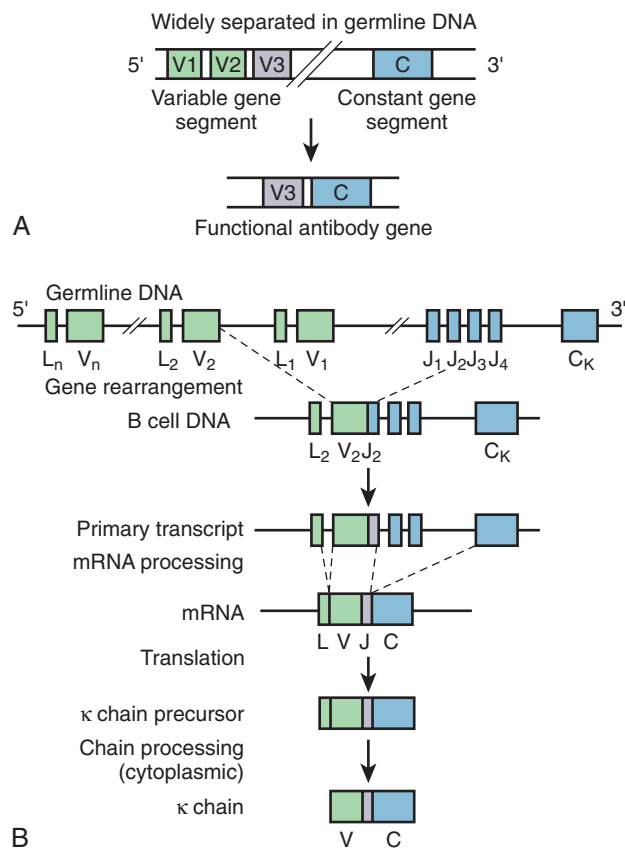

Figure 13-2 Principles of genetic recombination. **A**, In the germline DNA, the V region segments are located upstream from the D, J, and C segments on the same chromosome. Recombination, which takes place only in lymphocytes, brings the V gene segments in proximity to the downstream segments. **B**, In the B cell, rearrangement of gene segments separated in the germline DNA allows for the formation of a functional immunoglobulin light chain gene (compare with Fig. 13-1C). mRNA, messenger RNA. (Adapted from *MKSAP in the specialty of rheumatology*, Philadelphia, 1993, American College of Physicians, p 8.)

matching, and (3) somatic mutation of rearranged genes.⁹⁻¹¹ Another major force in shaping the antibody repertoire has been termed “receptor editing,” which allows receptors with self-reactive potential to be modified by additional recombination events during B-cell differentiation.^{12,13}

Figure 13-2A illustrates the principle of genetic recombination for an Ig gene.^{9,10} In this case, one of several variable (V) region gene segments (normally separated upstream from the constant [C] region gene segments on the same chromosome) can be linked to a single C region gene segment by genetic recombination. The combining of gene segments, rather than the existence of a single gene coding for every individual antibody molecule, considerably reduces the amount of genetic information required to encode many different antibody molecules. In Figure 13-2B the different gene segments that encode a κ light polypeptide chain are shown. Note that in this case, a V region rearranges proximal to a J segment, which is linked to the C region segment. Rearrangement of κ or γ light chain genes involves V, J, and C region gene segments (see Fig. 13-2A; see also Fig. 13-1C). In the formation of a functional heavy chain gene, a successful rearrangement of gene segments includes one V, one D, and one J region segment linked to a C region segment (compare Figs. 13-1C and 13-2B).

During genetic recombination, additional variability is generated by a process known as “junctional diversification.” When two gene segments are brought together during rearrangement, the linking is not precise. Instead, some nucleotides are inserted or deleted randomly at the junctional site. This introduces new codons, and therefore new amino acids, into the junctional sequence. If an incorrect number of junctional nucleotides are added or deleted, functional molecules will not be encoded, because the rest of the gene will be “out of frame” or a “stop” sequence will be introduced. Junctional diversification takes place in the hypervariable CDR3 region of the molecule (see Fig. 13-1C).

In general, a single B cell usually expresses an Ig molecule of only one antigen specificity, composed of one heavy chain molecule and one light chain molecule. Even though there are two chromosomal copies of the heavy chain genes in each cell, only one is usually functionally expressed. This phenomenon of using genes on only one parental chromosome is known as “allelic exclusion.” Once there has been a functional rearrangement of heavy chain genes on one parental chromosome, rearrangement of heavy chain genes on the other chromosome is mostly prevented. If the first rearrangement is not successful, the second one can take place. All of the genetic events described earlier happen before the B cell encounters its antigen. The B-cell (or antibody) response diversifies further after interaction with antigen by a process known as “somatic mutation,” primarily involving point mutations in the hypervariable regions of the V regions.^{10,11} Somatic mutation can be viewed as “fine tuning” of the antibody response, occurring after the primary response to a stimulus and during the development of memory B cells. It is, therefore, mostly observed during a secondary immune response. Somatic mutation allows for the production of antibodies with higher affinity for antigen, that is, the ability to bind more strongly to an antigen. Although the mutations are random, B cells with high affinity are selectively expanded (referred to as “affinity maturation”) because the stronger binding allows preferential stimulation by the target antigen. Somatic mutation is closely tied to isotype switching, and T-cell help is required. Somatic mutation usually takes place at the site of T-cell–B-cell interaction in the germinal centers of lymph node or spleen.

Isotype Switching and Function of the Different Immunoglobulin Classes

One B cell usually makes antibody of a single specificity that is fixed by the nature of V_LJ_L and $V_HD_HJ_H$ rearrangements. During the lifetime of this cell, however, it can switch from making an IgM molecule to producing a different class of antibody, such as IgG or IgA, while retaining the same antigenic specificity. This phenomenon is known as “class switching” or “isotype switching.”^{10,14}

Figure 13-3 shows the predominant mechanism by which a B cell switches from production of surface IgM to secretion of an IgG, IgA, or IgE molecule. The mechanism involves further DNA rearrangement (a process unique to Ig heavy chain genes), linking rearranged VDJ gene segments with a different heavy chain C region gene segment downstream. The switch (S) region is a stretch of repeating sequences 5' to the C region that allows a VDJ unit (previously linked to the C_μ region gene segment) to rearrange to

Figure 13-3 Genetic mechanisms involved in immunoglobulin (Ig) isotype switching. *Top*, The initial rearrangement of Ig heavy chain gene segments has already taken place in the B cell to put the V region proximal to the D, J, and C_μ segments. This latter genetic region contains other constant region gene segments farther downstream, including C_δ, various C_γ and C_α gene segments, and C_ε. In the process of T-cell-dependent B-cell activation in the germinal centers, the B cell is signaled to undergo isotype switching to allow high-rate secretion of an IgG1 antibody. *Bottom*, This is accomplished by additional DNA rearrangements that put the VDJ unit adjacent to the C_{γ1} segment downstream. The intervening DNA is deleted.

Table 13-4 Properties and Functional Characteristics of Immunoglobulin Classes and Subclasses*

Effector Function	IgM	IgD	IgG1	IgG2	IgG3	IgG4	IgA	IgE
Mean serum levels (mg/mL)	1.5	0.04	9	3	1	0.5	2.1	0.00003

another C region downstream. In the process the intervening DNA is deleted. The B cell therefore cannot return to IgM production. Class switching generally follows stimulation of the B cell by antigen and frequently is dependent on factors released by T helper cells.

Each class of secreted Ig has a different set of functions (Table 13-4).^{10,15} IgG is the major antibody of secondary immune responses and is most important for obtaining effective immunization to various toxins, toxoids, and certain extracellular pathogens. IgG accounts for 70% to 75% of the total Ig pool and is the major Ig class in normal human serum. It also crosses the placenta and confers immunity to newborns and neonates for the first few months of life. The interaction of IgG antibodies with antigen can have numerous consequences, including precipitation, agglutination, complement activation, and various cellular effector functions via IgG receptors.^{10,15-18} There are four IgG subclasses, with IgG1 and IgG3 being most effective at fixing complement and activating complement-mediated effector functions.

IgM is the predominant early-secreted antibody, frequently seen in primary immune responses. IgM is important for effective responses to antigenically complex infectious organisms, especially those with polysaccharide-containing cell walls. IgM antibodies may also be extremely effective at precipitation, agglutination, and complement activation after binding to antigen. Secreted IgM is usually found as a pentamer of the basic (four-domain) Ig unit. Polymerization is facilitated by the binding of the heavy chain tailpieces to a joining (J) peptide.

IgA plays a major role in mucosal immunity and is the predominant Ig in secretions such as saliva and tracheo-bronchial secretions. Secretory IgA exists mainly in dimeric form and contains a secretory component, which is synthe-

sized by epithelial cells and facilitates transport into secretions as well as protection from proteolysis. Secretory IgA is involved in the prevention of microbial adherence to mucosal cells and in the agglutination of microorganisms. IgA provides the first line of defense against a variety of pathogens.

IgE is scarce in the serum. Its major importance relates to its ability to bind to FcεR1 receptors on mast cells and basophils, and cross-linking of IgE bound to these cells results in cellular activation, degranulation, and release of mediators involved in allergic responses, such as histamine and various leukotrienes.¹⁹ IgE plays a role in immunity to parasites, but in developed countries, it is more commonly associated with allergic responses and allergic diseases, such as hay fever and asthma (see Chapters 41 and 42).²⁰

B-Cell Development

B cells are produced in the specialized microenvironments of the fetal liver and the adult bone marrow.²¹ After migration out of the bone marrow, the life span of mature naive B cells is limited unless there is contact with antigen. B cells interact with foreign antigen in the peripheral lymphoid tissues, particularly in the germinal centers of lymph nodes and spleen.²² The interaction with antigen, in the setting of T-cell help, results in the generation of memory B cells and cells that secrete a large amount of Ig. This frequently involves class switching and somatic mutation, which allows a secondary antibody response to generate antibodies of a different isotype with higher affinity for the stimulating antigen. An additional view of B-cell development is shown in eFig. 13-2.

The formation of the B-cell repertoire in the bone marrow is mostly random, and B cells with self-reactivity are generated. Negative selection of cells capable of strongly binding

to self-antigens is an important part of B-cell development. This process of B-cell self-tolerance involves both deletion (elimination) and functional inactivation (anergy) of self-reactive cells.²³ In addition, B cells with specificity for self-antigens can modify their receptors through a process called “receptor editing.”^{12,13} These self-reactive B cells undergo a reversible arrest of development and reinitiate light chain gene rearrangements to alter their BCR. If a B cell fails to edit its BCR, it is destined for cell death (apoptosis). Immature B cells in the bone marrow appear to be capable of receptor editing, whereas mature B cells in the peripheral lymphoid tissues normally lose this ability to initiate a new round of Ig gene rearrangements.

Immunoglobulin Interactions with Antigen

An antigen is a molecule or molecular complex recognized by B cells or T cells. The term *immunogen* usually refers to a substance capable of eliciting an immune response, and therefore it must also be capable of being recognized as an antigen. An antigen (e.g., a protein molecule) is usually much larger than the small region fitting into the binding site of an Ig molecule or the processed peptide recognized by a TCR. This smaller region is frequently referred to as an “antigenic determinant” or “epitope.” In a protein a B-cell epitope can theoretically be constructed in two ways—as a continuous or a discontinuous epitope. In a continuous epitope, the amino acid residues are part of a single uninterrupted sequence, whereas in a discontinuous epitope, residues are not contiguous in the primary structure but are brought together by the folding of the polypeptide chain. Because this kind of epitope requires a special conformation of the antigen, it is frequently referred to as a “conformational epitope.”

B cells and T cells usually recognize different parts of an antigen. B cells and their secreted Ig molecules most commonly recognize unprocessed or “native” antigens. These antigens have maintained their native configuration, and most of the epitopes are usually of the discontinuous or conformational type. In general, only a minor component of a B-cell response is directed to small linear peptide regions of the antigen. Studies indicate that epitopes recognized by B cells are not randomly distributed throughout the antigen but rather reside in regions with particular structural features. One important feature is “accessibility,” because epitopes normally must be on the outer surface of a protein and may protrude from an antigen’s globular surface to be able to interact with the BCR.

T CELLS AND ANTIGEN-PRESENTING CELLS

In contrast to B cells, T cells recognize processed pieces of a protein antigen, which are presented to the TCR by MHC molecules on the surface of antigen-presenting cells.^{4,5}

T-Cell Receptors

The TCR shows important structural similarities with Ig molecules (Fig. 13-4).³ The $\alpha\beta$ TCR is expressed by at least 90% of peripheral blood T cells. Essentially, all CD4⁺ T cells and most CD8⁺ T cells express this form of the TCR. A small percentage of $\alpha\beta$ -expressing T cells have a double-negative (CD4⁻ and CD8⁻) phenotype. As shown in Figure 13-4, each chain consists of two extracellular Ig-like domains anchored

Figure 13-4 The T-cell receptor (TCR) α and β chains indicate the regions encoded by different TCR gene segments. The positions of the complementarity-determining regions (CDRs) of both the β and the α chains are also shown. These are the most variable parts of the TCR and the most important for TCR binding to the peptide/major histocompatibility complex. CDR1 and CDR2 of both the α and the β chains are encoded within the variable region genes. CDR3 is formed by the rearrangement of V, D, and J gene segments of the β chain and V and J segments of the α chain and is encoded by the distal part of the V region segment through part of the J segment. The different parts of the TCR are not drawn to scale.

into the plasma membrane by a transmembrane region and a short cytoplasmic tail. Similar to Ig molecules, the outer NH₂-terminal domain of each chain constitutes the variable region. Outside of the transmembrane region, the two chains are covalently linked together by disulfide bonds. Due to the short cytoplasmic tail, the $\alpha\beta$ heterodimer is not capable of transmitting an intracellular signal after TCR engagement. This function is accomplished by the CD3 complex of polypeptides and other signaling proteins that are associated with the TCR.

The $\gamma\delta$ TCR is an alternative form of TCR that is similar in overall structure to the $\alpha\beta$ receptor.²⁴ Although some $\gamma\delta$ cells express CD8, most are CD4⁻ and CD8⁻ (double negative). CD8 expression is largely confined to those $\gamma\delta$ cells residing in the small intestine. The $\gamma\delta$ TCR is also expressed in association with the CD3 complex. Although $\gamma\delta$ T cells form a minor proportion of the T cells in the thymus and secondary lymphoid organs, they are abundant in various intraepithelial locations, such as in the skin, intestines, and lung.^{24,25}

T-Cell Receptor Structure and T-Cell Receptor Repertoire Formation

Genes encoding the TCR are organized similarly to Ig genes^{3,26} (eFig. 13-3). In a manner similar to that described previously for B cells, rearrangement of gene segments, junctional diversity, and combinatorial joining of the two chains is responsible for the diversity of the TCR repertoire. However, in contrast to B cells, TCR genes do not undergo somatic mutation. Thus nearly the entire TCR $\alpha\beta$ repertoire is formed during T-cell development in the thymus and before any interaction with antigen. Because the T-cell repertoire is shaped to recognize self-MHC antigens, it is believed that extrathymic somatic mutation might result in the generation of deleterious self-reactive T cells.

The components of the $\alpha\beta$ TCR heterodimer are shown in Figure 13-4, and the ribbon backbone structure of the $V\alpha$ and $V\beta$ portions of a human TCR are shown in Figure 13-5.^{4,5,27,28} The upward-pointing loop structures are the CDRs. These regions are the most variable part of the TCR α and β chains and are most important for binding of the TCR to the MHC/peptide complex. The CDR1 and CDR2 regions of the α chain and β chain are encoded within the germline *TCRAV* and *TCRBV* gene segments, and variability in their sequences distinguishes the different V region subfamilies. The most diverse part of the α and β chains is the CDR3, which directly interacts with peptide in the binding groove of the MHC molecule.

Figure 13-5 A ribbon backbone structure of the $V\alpha$ and $V\beta$ portions of a human T-cell receptor (TCR). The upward-pointing loop structures are the complementarity-determining regions (CDRs). These regions are the most variable part of the TCR α and β chains and are most important for TCR binding to peptide/major histocompatibility complex. The CDR1 and CDR2 regions of the α chain and β chain are encoded within the germline *TCRAV* and *TCRBV* gene segments, respectively. The highly variable CDR3 region is formed by the rearrangement of V, D, and J gene segments. Junctional nucleotide substitutions and deletions at the margins of rearrangement add to the potential diversity of the CDR3 region. (Adapted from Kotzin BL, Kappler J: Targeting the TCR in rheumatoid arthritis. *Arthritis Rheum* 41:1907, 1998.)

Antigen-Presenting Cells and the Major Histocompatibility Complex

There are two major varieties of MHC molecules (and genes) involved in the presentation of antigens to T cells.²⁹ MHC class I molecules include *human leukocyte antigen* (HLA)-A, HLA-B, and HLA-C molecules. MHC class II molecules include the HLA-DR, HLA-DQ, and HLA-DP molecules. Class I molecules are expressed on nearly all nucleated cells. In contrast, class II molecules have a limited distribution and are normally present only on cells involved in antigen presentation to T cells, including dendritic cells, macrophages, B cells, and thymic epithelial cells. The limited expression of class II antigens in different tissues may be extremely important in preventing various types of autoimmune reactions. After activation or exposure to certain cytokines, such as *interferon- γ* (IFN- γ), other human cell types such as activated T cells and epithelial cells can express class II molecules.

The general structures of the two classes of MHC molecules are shown in Figure 13-6. For MHC class I antigens, the α chain (encoded within the MHC) is complexed to β_2 -microglobulin (encoded outside the MHC). The α chain is highly polymorphic (variable between individuals), whereas β_2 -microglobulin is invariant. The extracellular portion of the α chain is divided into three domains: $\alpha 1$, $\alpha 2$, and $\alpha 3$. The outer $\alpha 1$ and $\alpha 2$ domains represent the polymorphic components of the molecule, and the $\alpha 3$ domain is relatively constant. MHC class II molecules are composed of an α and a β chain, both of which are encoded within the MHC. The NH_2 -terminal domains of each chain ($\alpha 1$ and $\beta 1$ domains) represent the polymorphic regions of the molecule and are important in antigen presentation, whereas the $\alpha 2$ and $\beta 2$ domains are relatively constant.

The structures of MHC class I and class II molecules have provided remarkable insight into how antigenic peptides are bound and presented to T cells.^{4,5,30-33} In Figure 13-7A, the peptide-binding groove of a class I molecule is viewed from the top, showing the surface that is contacted by a TCR. MHC class I pockets can usually only bind peptides of 8 to 10 amino acids, which are bound in a typical extended conformation with both the NH_2 terminus and the *carboxy* (COOH) terminus anchored in the peptide-binding groove. In the case of MHC class II, the peptide-binding groove is

Figure 13-6 Comparison of the composition of class I and class II major histocompatibility complex (MHC) molecules. The class I MHC α chain is variable (polymorphic) among different individuals. It is expressed with β_2 -microglobulin, which is encoded outside the MHC region and does not differ among different individuals. The class II MHC molecules are composed of α and β chains. For human leukocyte antigen (HLA)-DR molecules, only the β chain is variable, whereas for the HLA-DQ and HLA-DP molecules, both the α and the β chains are encoded by polymorphic alleles. In class I MHC molecules, the peptide-binding region is formed between the $\alpha 1$ and the $\alpha 2$ domains, which are polymorphic. The peptide-binding region of class II MHC is formed between the $\alpha 1$ and the $\beta 1$ domains of the α and β chains, respectively.

Figure 13-7 Structure of the major histocompatibility complex (MHC)/peptide complexes. **A**, A schematic view of an MHC class I binding groove with peptide. The peptide is shown in ball-and-stick representation. In class I molecules, the peptide is usually of fixed length (8–10 amino acids) and bound so that both the NH₂ and COOH termini are anchored in the peptide-binding groove. **B**, A schematic view of an MHC class II (human leukocyte antigen [HLA]-DR1) molecule with bound peptide in the groove. The peptide is shown in ball-and-stick representation. The peptide has the typical polyproline extended helical conformation seen in all class II bound peptides. The structure of class II allows peptides of varying lengths to bind because both ends of the peptide are free and can extend out of the groove on both sides. (From Jones EY: MHC class I and class II structures. *Curr Opin Immunol* 9:76–77, 1997.)

formed by the interaction of the NH₂-terminal domains of the α and β chains (see Fig. 13-7B). The structure of MHC class II allows peptides of varying lengths to bind because both ends of the peptide are free, and the peptide shown in Fig. 13-7B has the typical polyproline-like extended helical conformation seen in all class II MHC-bound peptides.

Presentation and T-Cell Recognition of Antigens

In contrast to B cells, T cells recognize processed peptides of a foreign antigen that are complexed to MHC molecules on antigen-presenting cells. Because of the process of thymic selection for self-MHC recognition, there is little capability for T cells to recognize intact or native protein antigens. CD4⁺ T cells generally recognize peptides complexed to class

Figure 13-8 T-cell recognition of a conventional peptide antigen. The major histocompatibility complex (MHC) molecule on the antigen-presenting cell (brown) shows the peptide-binding groove with a peptide in it. The interacting TCR is shown as a blue structure. Note that the junctional regions of the TCR α chain ($V\alpha/J\alpha$) and β chain ($V\beta/D\beta/J\beta$) are depicted so that they appear to have the most important interaction with the peptide. These junctional regions form the complementarity-determining region (CDR) 3 of the α and β chains, which is the most variable component of the TCR. The CDR1 and CDR2 loops are encoded within the $V\alpha$ and $V\beta$ regions and may have more interaction with the MHC parts of the complex compared with CDR3. A ribbon diagram of the TCR CDR loops is depicted in Figure 13-5. (Adapted from Drake CG, Kotzin BL: Superantigens: biology, immunology, and potential role in disease. *J Clin Immunol* 12:140, 1992.)

II MHC molecules, whereas CD8⁺ T cells interact with peptide/class I MHC molecules.^{3–5,29} The purpose of this relatively complex antigen-presentation process may be to focus the T-cell response onto cells. For example, it is much easier for a T cell to kill a virus-infected cell before the pathogen has the opportunity to multiply than it is to kill individual virus particles. The class I MHC molecules therefore focus the cytotoxic T-cell response on cells infected with intracellular organisms, whereas free infectious particles are the targets of antibodies. Class II MHC molecules similarly focus the delivery of T-cell help on the relevant antigen-specific B lymphocytes that eventually produce antibodies. Recognition of antigen only on the surface of MHC class II-expressing cells also allows for a system by which the activation of CD4⁺ T cells can be closely regulated.

Peptide-containing MHC class I and class II molecules on the surface of antigen-presenting cells serve as ligands for TCRs of CD8⁺ and CD4⁺ T cells, respectively. To present antigenic peptides effectively, antigen-presenting cells must be capable of performing at least two functions: (1) processing and displaying parts of antigens in the peptide-binding groove of MHC molecules on their cell surface and (2) providing the other accessory signals necessary for T-cell activation. Antigen processing refers to the series of steps that generate these peptide fragments, load them onto MHC molecules, and allow expression of the peptide/MHC complex on the cell surface.³⁴ Major differences exist in the manner in which endogenous and exogenous foreign antigens are processed and presented to T cells,^{34–39} which are beyond the scope of this chapter.

Figure 13-8 shows a schematic view of antigen recognition by a CD4⁺ T cell. A foreign peptide is contained within the antigen-binding groove of a class II MHC molecule, and the TCR simultaneously recognizes the complex of peptide and class II MHC molecule. Thus residues of the variable

region of the TCR interact with the peptide and MHC residues extending out from the peptide-binding groove. The highly variable CDR3 region of the $\alpha\beta$ TCR is frequently most important in the binding of peptide, whereas other parts of the variable regions are more involved in MHC residue interactions.³⁻⁵

Development and Selection of the TCR Repertoire

Stem cells pre-committed to the T-cell lineage arise in the bone marrow and migrate to the thymus. See eFig. 13-4 for additional information on T-cell development and maturation. These cells do not express TCR molecules and do not express CD4 or CD8 molecules. These cells develop by rearranging TCR α and β chain genes and generating a functional $\alpha\beta$ TCR. In the thymus, two major processes modify this repertoire.⁴⁰⁻⁴² One process positively selects cells that have some TCR affinity for self-MHC molecules. Evidence suggests that an interaction with thymic cortical epithelial cells is involved in this positive selection step. This process allows mature cells to eventually recognize foreign antigens in the context of self-MHC antigens (a phenomenon termed “self-MHC restriction”). Cells that are not positively selected undergo programmed cell death (apoptosis) within the thymus. The other process deletes cells that have a high level of self-reactivity (termed “negative selection” or “self-tolerance”).⁴² This deletion process primarily involves an interaction with bone marrow–derived cells (macrophages, dendritic cells, B cells) that have migrated to the thymus and specialized cells within the thymic medulla (medullary epithelial cells) that express a variety of organ-specific antigens.^{43,44} The transcriptional regulator, Aire, plays an important role in T-cell tolerance induction in the thymus, mainly by promoting ectopic expression of a large repertoire of transcripts encoding proteins normally restricted to differentiated organs in the periphery.⁴⁴ Only a small percentage ($\approx 1\%$ to 3%) of thymocytes actually survive positive and negative selection and become mature thymocytes that have a relatively high level of TCR expression and express either CD4⁺ or CD8⁺ markers. In general, cells that are positively selected by an interaction with class II MHC molecules mature into the CD4 population, whereas cells that are positively selected on class I MHC molecules become the CD8 population.⁴⁵ Mature thymocytes subsequently migrate to peripheral lymphoid tissues, where they maintain these surface characteristics.

T-Cell Tolerance: Prevention of Self-Reactivity

Tolerance at the T-cell level is critical for the prevention of autoimmunity. Clonal deletion of self-reactive T cells in the thymus is a major process for eliminating T cells that are reactive to non-organ-specific cellular proteins and to circulating proteins, because these self-antigens are likely to be in the thymus during T-cell development. Some organ-sequestered antigens (e.g., certain uveal tract, brain, and endocrine organ antigens) are also expressed in the thymus.^{43,44} However, studies have clearly shown that T cells to various self-antigens, including many organ-sequestered and posttranslationally modified antigens, are not completely deleted in the thymus. Therefore self-tolerance must also involve the prevention of activation of these autoreactive T cells after they migrate from the thymus to the peripheral lymphoid tissues.^{46,47}

Studies have shown that T cells with self-reactive TCRs are present in the peripheral lymphoid organs and the circulation of healthy individuals, but they are not sufficient for the development of autoimmune disease. Different peripheral mechanisms appear to help prevent the generation of autoimmune responses. One process appears to prevent the self-antigen from being effectively presented to a self-reactive T cell, which maintains that T cell in an ignorant state. For example, resting T cells with self-reactive potential may not be able to traffic to the tissue that expresses the antigen, or the antigen may not be presented by effective antigen-presenting cells. Some studies have suggested that inappropriate expression of class II antigens in a tissue can lead to autoimmunity, perhaps by circumventing this protective mechanism. T-cell activation triggered by a separate process (e.g., an infectious agent) may also bypass this protective mechanism by allowing cells with self-reactive potential to traffic to tissues inappropriately. T cells that do recognize antigen without effective antigen-presenting cells and co-stimulation may also be functionally deactivated (or anergized)⁴⁸ and prevented from any subsequent stimulation by that self-antigen. These cells continue to be present in the peripheral T-cell repertoire, but their prior contact with self-antigen prevents any subsequent response. Current evidence indicates that anergic T cells activate some but not other signaling pathways after TCR engagement.⁴⁸ There is also evidence that the encounter of self-reactive T cells with antigen, but without effective presentation, sometimes leads to death of the autoreactive T cell rather than just anergy.

A final mechanism to prevent activation of self-reactive T cells involves regulatory (suppressor) T cells. In experimental animal models, there is evidence that CD4⁺, CD8⁺, and $\gamma\delta$ T cells may be involved in the down-regulation of certain immune responses, and their absence may be associated with pathologic autoimmune responses. At least two subsets of regulatory CD4⁺ T cells have been described that can inhibit cell-mediated immune responses and autoimmune pathologic responses: naturally occurring cells with suppressive activity and those induced by stimulation.^{49,50} The naturally occurring regulatory CD4⁺ T cells are characterized by constitutive CD25 expression and constitute 5% to 10% of the circulating CD4⁺ population.⁴⁹⁻⁵² In murine models, depletion of these CD4⁺CD25⁺ T cells results in the spontaneous onset of multiorgan autoimmunity. These cells mediate their suppressive effects in a contact-dependent, antigen-independent manner in the absence of *interleukin-10* (IL-10) or *transforming growth factor- β* (TGF- β). A novel member of the forkhead box/winged-helix family of transcription regulators, designated FOXP3, has been identified as a specific molecular marker for this type of regulatory T cell, and its expression is essential for programming both thymic development and function of these T cells.^{49,53} In sarcoidosis, FOXP3-expressing regulatory T cells accumulate at the periphery of the granuloma in subjects with active disease.⁵⁴ However, despite suppressing mitogen-induced T-cell proliferation, the regulatory T cells in lung could not completely suppress *tumor necrosis factor- α* (TNF- α) and IFN- γ secretion, suggesting that the activity of this regulatory T-cell subset was incapable of controlling granulomatous inflammation. The other type of regulatory CD4⁺ T cell is activation induced, and these cells lack CD25

and FOXP3 expression.⁴⁹ Much of the suppression from this group of regulatory cells can at least in part be attributable to cytokines such as TGF- β , because TGF- β is capable of suppressing both *type 1* (Th1) and *type 2* (Th2) *T helper* cell responses (see Th1 and Th2 responses, later). It is relevant to note that mice deficient in TGF- β show evidence of progressive inflammation and autoimmunity involving multiple organs.⁵⁵ In some cases, regulatory CD4⁺ T cells appear to release cytokines, such as IL-10 or even IL-4, that modulate the development and activation of Th1-type cells involved in a cell-mediated response.^{50,56,57}

GENERATION OF AN IMMUNE RESPONSE

T-CELL ACTIVATION AND CO-STIMULATION

Most immune responses depend on the activation of T cells, and normally, immune responses to foreign antigens are carefully orchestrated by a reciprocal communication between antigen-specific T cells and antigen-presenting cells. To be activated, naive T cells must receive several signals. One signal is antigen specific and is provided by engagement of the TCR. Additional signals are provided by co-stimulatory molecules and their interactions (Fig. 13-9). Resting antigen-presenting cells, such as resting B cells, frequently do not express significant levels of co-stimulatory molecules, and their interaction with T cells does not lead to T-cell activation. Two of the most important co-stimulatory systems involve the interaction of CD28 with B7-1 (CD80) and B7-2 (CD86) and the interaction of CD40 ligand with CD40.⁵⁸ These two systems of interacting molecules also affect each other.

CD28 is constitutively expressed on CD4⁺ T cells. Early in the immune response, B7-1 and B7-2 are up-regulated

on the antigen-presenting cells. Binding of CD28 to B7 co-stimulates T-cell activation, leading to increased T-cell production of IL-2 and other cytokines, increased cytokine receptor expression, increased cell survival, and increased T-cell proliferation.⁵⁹⁻⁶¹ Occupation of the CD28 receptor alone, without TCR engagement, has little effect on T cells; therefore signaling through CD28 is clearly a co-stimulatory event. The intracellular signaling that follows CD28 co-stimulation may overcome certain negative signals generated when the TCR is activated alone.^{58,62,63}

Presentation in an inflammatory setting also leads to up-regulation of CD40 ligand (CD154) on the CD4⁺ T cell.⁶⁴ CD40 ligand interacts with its counter-receptor, CD40, on B cells and other antigen-presenting cells, also inducing up-regulation of B7-1 and B7-2 as well as certain adhesion molecules and cytokine production by the presenting cell.⁶⁵ The interaction of CD40 ligand with CD40 is clearly bidirectional in that it provides signals important for T-cell and B-cell activation. CD40 ligand is a member of the TNF receptor family, and a variety of other TNF receptor family members, such as CD134 (OX40), CD137 (4-1BB), and CD27, have also been shown to possess co-stimulatory function following T-cell activation.^{58,66} In chronic beryllium disease, CD137 has recently been shown to be a critical co-stimulatory molecule for the induction of T-cell proliferation and prevention of activation-induced cell death in effector CD4⁺ T cells in lung.⁶⁷

Following activation, T cells express *cytotoxic T lymphocyte antigen-4* (CTLA4) on their surface, which also binds B7-1 and B7-2 on the antigen-presenting cell and with stronger affinity than CD28.⁶⁸ This interaction sends a negative signal to down-regulate the T-cell response after its initial activation. CTLA4 appears to be involved in the development of anergy and the generation of peripheral tolerance. CTLA4-deficient mice develop a lymphoproliferative disorder and die early, and alterations in the gene encoding

Figure 13-9 T helper cell–B-cell interactions important for T-cell–dependent antibody production. Antigen cross-links membrane immunoglobulin (Ig) on the B-cell receptor (BCR), which provides the first signal for the B cell. CD79a (Ig- α) and CD79b (Ig- β) are Ig-accessory molecules necessary for transmitting the signal intracellularly. The antigen is internalized into an intracellular compartment in the B cell, processed to peptides, and combined with major histocompatibility complex (MHC) class II molecules for expression and presentation to the T helper cell. T-cell receptor (TCR) binding to the peptide/MHC provides the first signal for the T cell. The CD3 complex and ζ chains allow for the TCR signal to be transmitted intracellularly. Activation of the T cell results in expression of CD40 ligand (CD40L), OX40, and 4-1BB. Interaction with CD40 provides the most important second signal to the B cell and is involved in T-cell activation. In addition, B7-1 (CD80) and B7-2 (CD86) are up-regulated on the B cell. Interaction with CD28 provides an important co-stimulatory signal to the T cell. This figure does not show the release of cytokines from the T helper cell that are necessary for full activation and differentiation of the B cell. In addition, this figure does not show other cellular interactions mediated by adhesion molecules. For example, the leukocyte function antigen (LFA)-1 integrin (CD11a, CD18) on the T cell interacts with intercellular adhesion molecule-1 (CD54) on the B cell. This interaction appears to be enhanced once the TCR and BCR have been engaged. CD2 on the T cell also interacts with LFA-3 on the B cell, which provides additional cell-cell adhesion.

Figure 13-10 Regulation of T helper cell activation and responses. Naive CD4⁺ T cells can develop into type 1 T helper (Th1) cells if they are activated in the presence of interleukin (IL)-12, produced mostly by macrophages and other non-T cells. Interferon- γ (IFN- γ), increased by IFN- γ -inducing factor (IL-18), also enhances the development toward a Th1 response. IFN- γ appears to increase the production of IL-12 and also the expression of receptors for IL-12. The generation of a Th1 response leads to the production of IL-2, IFN- γ , lymphotoxin tumor necrosis factor- β (TNF- β), and tumor necrosis factor- α (TNF- α). These inflammatory cytokines are important for a successful immune response to intracellular pathogens. Inappropriate Th1 responses have also been implicated in organ-specific autoimmunity such as in type 1 diabetes, multiple sclerosis, and rheumatoid arthritis. The early presence of IL-4 in the activation of a helper cell prevents Th1 responses and enhances the development of a type 2 T helper cell (Th2) response. The source of the early IL-4 is not clear, but it may come from Th2 cells already present, natural killer 1⁺ T cells, or non-T cells, such as mast cells and eosinophils. The Th2 response results in production of IL-4, IL-5, IL-10, and IL-13 and enhances humoral immunity. Although the Th2 cells are critical for the immune response to helminths, in the developed world, Th2 cells are probably most singled out for their important role in allergic disease and asthma. IL-4 and IFN- γ inhibit the development of a type 17 T helper cell (Th17) response that promotes bacterial clearance and may play a role in the development of autoimmunity. IL-6 and transforming growth factor- β (TGF- β) promote the development of Th17 cells, whereas IL-23 expressed by macrophages augments expression of Th17 cytokines by memory but not naive CD4⁺ T cells. Various regulatory CD4⁺ T cells have also been described. Regulatory CD4⁺ T cells secreting TGF- β have the capability to suppress both Th1 and Th2 responses. Evidence suggests that, in addition to the cytokines present at the time naive CD4⁺ T cells are stimulated, the type of dendritic cell may regulate the differentiation of CD4⁺ T cells into Th1, Th2, or Th17 subsets.

CTLA4 have been associated with autoimmune endocrine diseases, further emphasizing the role of CTLA4 in the control of lymphocyte homeostasis.^{69,70} Programmed cell death 1 is another activation-induced inhibitory receptor that is expressed by T cells and binds B7 family members.⁷¹ Similar to CTLA4, programmed cell death 1 receptor engagement results in down-regulation of the immune response. Deficiencies of this gene have been associated with autoimmune diseases in animals and may be a possible gene contribution to human lupus.^{72,73} In addition to these negative signals, down-regulation of the T-cell response may be further ensured by decreases in surface expression of CD40 ligand, OX40, and 4-1BB after T-cell activation.^{61,66}

As discussed earlier in the context of self-tolerance, engagement of the TCR on a naive T cell in the absence of co-stimulation can result in different outcomes.⁵⁸ In some situations the outcome is a failure to stimulate, and the T cell is oblivious to this encounter. At other times, recognition can induce death (apoptosis) of the responding T cells or anergy, in which case the T cells are unable to respond to a subsequent encounter with the same antigen (tolerance). Memory T cells appear to be less dependent on co-stimulatory molecules. However, antagonists that interrupt co-stimulatory interactions have been shown to have profound effects even later in the course of an established immune response. Blockers of the CD28-B7 interaction (with CTLA4-Ig, anti-B7, or anti-CD28 monoclonal antibodies) or of the CD40 ligand-CD40 interaction

(with anti-CD40 ligand monoclonal antibodies), separately and together, are being investigated as therapies to treat autoimmune diseases and alloreactive responses after transplantation.⁷⁴⁻⁷⁷ However, the recent development of cytokine storm in healthy volunteers receiving an anti-CD28 monoclonal antibody demonstrates the potential risk of immunotherapy.⁷⁸

SUBSETS OF T HELPER CELLS

Although more sharply defined in mice than in humans, it is clear that T cells after activation may evolve into at least three major subsets of T helper cells, distinguished by their secreted cytokines (Fig. 13-10).^{40,56,57} Th1 cells mainly synthesize IL-2, IFN- γ , and TNF- α , as well as other inflammatory cytokines, such as lymphotoxin. Th2 cells primarily are distinguished by their secretion of IL-4, IL-5, and IL-13. Th17 cells represent a distinct lineage of T cells from either Th1 or Th2 cells and express IL-17A, IL-17F, and IL-22.⁷⁹⁻⁸² These major types of T helper cells appear to serve very different functions. Th1 cells primarily enhance cell-mediated immune responses, such as delayed-type hypersensitivity reactions, which frequently involve activation of macrophages and effector T cells. Th2 cells mainly provide help for B cells by promoting class switching and enhancing the production of certain IgG isotypes and production of IgE. The ability to mediate an effective immune response against certain intracellular pathogens and the pathogenesis of certain diseases appear to be strongly influenced by the

type of T helper cells involved. For example, in leishmaniasis and leprosy the development of a response polarized toward the Th1 pathway is important for successful immune defense. The development of an early Th2 response may result in the inability to clear the offending organism. Inappropriately developed and activated Th1 cells have been implicated in the pathogenesis of certain autoimmune diseases, such as type 1 diabetes, multiple sclerosis, and rheumatoid arthritis. Th2 cells appear to be important for certain immune responses.²⁰ Eradication of helminths is Th2 dependent. However, Th2 cells also appear to be involved in disease by driving allergic responses, such as IgE production and eosinophil activation in asthma (see Chapter 41).²⁰ Th17 cells function at the interface between the innate and adaptive immune response, secreting cytokines that are important in bacterial clearance and in the pathogenesis of autoimmunity. Evidence suggests that in collagen-induced arthritis, T-cell-mediated colitis, and experimental autoimmune encephalitis, Th17, as opposed to Th1, cytokines are critical for the induction and maintenance of inflammation.⁸³⁻⁸⁵

Th1, Th2, and Th17 subsets develop from the same T-cell precursor, which is a naive CD4⁺ T lymphocyte producing mainly IL-2 after stimulation with antigen. Considerable evidence indicates that the cytokine microenvironment is the primary determining factor for Th1, Th2, or Th17 differentiation (see Fig. 13-10).^{40,56,57,79,80} IL-12 and IFN- γ are most important in directing the development of Th1 cells that then go on to produce IFN- γ and TNF- α . IL-12 is produced by antigen-presenting cells (e.g., macrophages and dendritic cells) in response to Toll-like receptor stimulation by pathogens. IL-12 drives Th1 differentiation through signal transducer and activator of transcription 4 and the activation of a unique Th1 transcription factor known as T-box expressed in T cells.^{86,87} Microbial products frequently induce macrophages and NK cells to release IFN- γ , which is involved in driving development of Th1 cells from their naive precursors. IFN- γ up-regulates a component of the IL-12 receptor on naive and differentiating T cells.⁸⁸ However, some organisms, such as the measles virus, have the ability to down-regulate IL-12 production by macrophages and therefore possibly evade destruction by cell-mediated immune responses. Early production of IFN- γ by Th1 cells and NK cells has been related to the production of IFN- γ -inducing factor (IL-18), and this cytokine may synergize with IL-12 for maximal early production of IFN- γ and Th1 development.

In a similar but opposite manner, the presence of IL-4 early in the immune response induces Th2 cell development from naive precursors through signal transducer and activator of transcription 6, which leads to activation of the transcription factor GATA3 and up-regulation of IL-4 and IL-5.^{87,89} The effects of IL-4 in inducing Th2 development are dominant over Th1- and Th17-polarizing cytokines.^{56,57,90} Thus, if IL-4 levels exceed a threshold, Th2 development ensues, which leads to additional IL-4 production. Th2 cells do not respond to IL-12, which may be related to the ability of IL-4 to down-regulate expression of a component of the IL-12 receptor.

TGF- β and IL-6 are necessary for the differentiation of naive CD4⁺ T cells into Th17 cells.⁹⁰⁻⁹³ The retinoic acid

orphan nuclear receptor is the master transcription factor in the differentiation of Th17 cells.⁹⁴ Expression of retinoic acid orphan nuclear receptor is TGF- β and IL-6 dependent and is both necessary and sufficient to induce Th17 development in most CD4⁺ T cells.⁷⁹ Unlike T-box expressed in T cells and GATA3, the ligand of retinoic acid orphan nuclear receptor remains unknown. Using an IL-6-independent pathway, IL-21 and TGF- β can induce Th17 cells. IL-21 is also highly expressed by Th17 cells, and IL-21 production creates a positive feedback loop to amplify Th17 responses in vivo.⁹⁰ Despite the finding that IL-23 signaling is not required for Th17 commitment and early IL-17 secretion, IL-23 is important in amplifying and/or stabilizing the Th17 phenotype.⁷⁹

The cytokines produced by Th1, Th2, and Th17 subsets cross-regulate one another's development and function. For example, IFN- γ produced by Th1 cells inhibits the development of Th2 and Th17 cells as well as certain humoral responses.^{56,57,87} In a similar manner, IL-4 produced by Th2 cells inhibits Th1 and Th17 development and activation as well as macrophage activation by Th1 cytokines. IL-4 and IL-10 inhibit IL-12 production by dendritic cells and macrophages. In addition, it is possible that the transcription factors GATA3 and T-box expressed in T cells antagonize the development of the opposite T-cell subset by directly opposing each other's expression.^{87,89} TGF- β also inhibits the development of Th1 and Th2 phenotypes.⁸⁷

Following antigen exposure, naive T cells become activated, proliferate, and migrate to sites of inflammation. Although the majority of antigen-primed cells die, a population of memory T cells develops, which allows for a more rapid and effective secondary immune response upon reexposure to antigen.^{95,96} There are at least two subsets of memory T cells, possessing different functional and migratory capabilities compared with naive lymphocytes. The effector memory T cell represents a terminally differentiated cell that immediately produces cytokine following antigen exposure and lacks the lymph node homing receptors L-selectin and CCR7. Conversely, central memory T cells express L-selectin and CCR7 and can differentiate into effector memory cells after restimulation.

CD4⁺ T-CELL-B-CELL COLLABORATION AND REGULATION OF ANTIBODY PRODUCTION

A central event in the immune response is the antigen-specific interaction between a T helper lymphocyte and a B lymphocyte, which leads to their mutual activation. Although some antigens (usually nonproteins derived from bacteria) can activate B cells in a T-cell-independent fashion, the antibody response to most protein antigens requires that the relevant B cell must recognize antigen with its surface Ig receptor and receive certain activation signals from a CD4⁺ T helper cell. These signals include both secreted T-cell-derived lymphokines and those resulting from cell-cell contact. T-cell recognition of antigenic peptides bound to class II MHC molecules on the B-cell surface and co-stimulatory signals lead to T-cell activation and secretion of T helper lymphokines. Secretion is directed toward the site of contact with the B cell. Thus far, no combination of known T-cell-derived factors can fully replace

contact with the T helper cell, indicating that the interaction of surface molecules provides additional signals to the B cell that promote its activation. Numerous interacting molecules have been identified that could transmit signals in the T-cell–B-cell interaction (see Fig. 13-9).

Similar to the process of effective T-cell stimulation, which requires interaction of TCR with MHC/peptide and co-stimulatory signals, B cells also need more than one signal for activation to take place. The first signal is provided by antigen binding to surface Ig (BCR), and cross-linking of multiple receptors is usually required. The B cell then processes and presents the antigen via its class II MHC molecule to a cognate T helper cell that is specific for that MHC/peptide complex. A major second signal to the B cells is provided via CD40 on its surface through interaction with up-regulated CD40 ligand on the T helper cell. After receiving additional co-stimulatory signals from up-regulated B7-1 and B7-2 on the B cells, the activated T helper cell delivers cytokines in a focused manner to the antigen-specific B cell it is helping. Although many reciprocal receptor-ligand pairs are expressed on T cells and B cells, the signaling between CD40 ligand and CD40 has emerged as an obligatory and nonredundant interaction for functional T-cell–dependent B-cell activation to proceed.⁷⁵ The signals transduced by CD40 are essential for the prevention of apoptosis of antigen-specific B cells in the germinal center and required for B-cell proliferation and differentiation, isotype switching, and formation of memory B cells. Mutations in the CD40 ligand gene cause X-linked hyper-IgM syndrome, characterized by absent or low levels of IgG, IgA, and IgE (Ig isotypes that require T-cell help) but normal or elevated levels of IgM. Because T-cell activation also requires co-stimulatory signals through CD40 ligand, these individuals demonstrate defects in T-cell-mediated immunity and defective T-cell activation.⁹⁷

T-cell help is required for effective antibody responses, especially those involving specific high-affinity antibodies of the IgG, IgA, and IgE isotypes. However, as emphasized earlier, T-cell–B-cell signaling is clearly bidirectional. After resting T cells are activated, which frequently requires specialized antigen-presenting cells such as dendritic cells, antigen-specific B cells may be the most efficient presenters of determinants of a specific antigen.⁹⁸ The helper CD4⁺ T cell recognizes a processed antigen presented on the B cell in the context of class II MHC antigens. The B cell focuses antigen for antigen-specific help by binding antigen through its Ig receptor, internalizing and processing the antigen, and presenting the derived peptides with class II MHC molecules (see Fig. 13-9). It is important to emphasize that the epitope on the native antigen recognized by the B cell is almost always different from the peptide epitope recognized by the helper CD4⁺ T cell.

Subsequent to T-cell recognition, the T cell is activated, and help for B-cell proliferation and differentiation can be provided. T-cell help is critically dependent on the T-cell release of various cytokines, as described earlier. These cytokines have marked effects on B-cell maturation, especially in determining which isotypes will be produced by the B cell. The reciprocal surface molecular interactions, the directed nature of T-cell cytokine release, and the controlled local action of these molecules result in “focused T-cell

help” without generalized bystander activation of surrounding B cells.

GENERATION AND REGULATION OF CELL-MEDIATED IMMUNE RESPONSES

Cell-mediated cytotoxicity is an essential defense against intracellular pathogens, including viruses and certain bacteria and parasites. Cytotoxic T cells are stimulated by presented endogenous antigens, most of them derived from intracellular pathogens and associated with class I MHC molecules. In contrast to most helper cells that express CD4, cytotoxic T cells are usually CD4[−]CD8⁺. The recognition of the antigen presented by class I MHC molecules triggers the T cell to express receptors for IL-2. Although some cytotoxic lymphocytes are able to produce their own IL-2, most depend on IL-2 produced by helper CD4⁺ T cells of the Th1 type. The binding of IL-2 and possibly other cytokines leads to some proliferation and to the development of cytotoxic function. CD4⁺ T helper cells (Th1 type) provide additional signals and cytokines for the generation of a maximal cytotoxic response.

Activated effector cells are capable of delivering a lethal message to a target cell, separating from their dying target, and moving on to strike a new target. This creates a very efficient system of killing unwanted cells. Several mechanisms are involved in the actual killing process.⁹⁹⁻¹⁰² For example, cytotoxic T cells can directly signal their targets to undergo apoptosis through the interaction of FAS ligand, expressed on the surface of activated T cells, with FAS on the target cell. The cytotoxic T cell also produces substances such as lymphotoxin (TNF-β), trimers of which bind to receptors on the cellular targets and signal for apoptosis. During binding to the target cell, the cytotoxic CD8⁺ T cells also release the contents of their granules, which include perforins and granule-associated serine esterases (granzymes), toward the adjacent membrane of the target cell. Released perforins assemble on the surface of the target cell and perforate the target cell plasma membrane, resulting in lysis and the entry of enzymes. The transmembrane channel created by the perforins resembles the membrane attack complex of the complement cascade. After entry into the target cell, activated granzymes released from the cytotoxic T cell activate proteins that mediate apoptosis and cause other types of cell damage.

SPECIFIC IMMUNE RESPONSES IN THE LUNG

LYMPHOCYTE POPULATIONS AND TRAFFICKING IN THE LUNG

The lung in healthy individuals usually harbors only a small number of lymphocytes.^{103,104} The location of CD4⁺ and CD8⁺ αβ T cells can be arbitrarily separated into four compartments: bronchoalveolar space, bronchus-associated lymphoid tissue (BALT), lung interstitial tissues, and intravascular space. Although lymphocytes from these different positions may be involved in lung immune responses, there is no clear indication that these cells represent a

resident lymphocyte population in the lung in humans. More likely, these lymphocytes belong to the recirculating lymphocyte pool. In contrast, $\gamma\delta$ T cells have been localized to intraepithelial positions in the lung, and these cells may selectively reside in the lung.²⁵

In a normal nonsmoking individual, lymphocytes account for approximately 10% to 15% of the bronchoalveolar cells obtained during bronchoalveolar lavage.¹⁰⁴ The number of bronchoalveolar lymphocytes can increase markedly in inflammatory diseases involving the alveoli and the interstitium, such as in sarcoidosis and hypersensitivity pneumonitis (see Chapters 64 and 66). Most bronchoalveolar lymphocytes are T cells, and essentially all of these cells express memory cell markers (e.g., CD45RO and low CD62L), indicating previous activation.¹⁰⁵ In disease, a significantly increased percentage of these T cells, compared with those in peripheral blood, also express markers of recent activation, such as HLA-DR, IL-2 receptor (CD25), and CD69.

BALT is a localized collection of lymphocytes in the subepithelial area of bronchi, analogous to gut-associated lymphoid tissue (e.g., Peyer patches).¹⁰⁶ These lymphoid aggregates are separated from the airway lumen by a lymphoepithelium composed of flattened epithelial cells, which lack cilia. BALT also contains HEVs facilitating the recirculation of lymphocytes between blood and lymph. However, unlike gut-associated lymphoid tissues in the form of Peyer patches, which are present in all mammals, BALT is found only in some mammalian species. Indeed, it is usually absent in humans as long as there is no respiratory tract infection. Evidence suggests that BALT may appear in patients after chronic airway inflammation and chronic obstructive pulmonary disease.^{107,108}

The interstitium of the normal lung contains few lymphoid cells, and most of these are not T cells. The majority of interstitial lymphocytes are NK cells, which constitute 10% to 15% of circulating lymphocytes. These cells do not express TCR or Ig but express markers characteristic of both T-cell and myelomonocytic lineages.⁷ NK cells recognize and kill tumor cells and virus-infected cells in a nonspecific manner.⁷ These cells also kill targets coated with antibodies via surface receptors for IgG (FCGR3 or CD16) in a process known as “antibody-dependent cellular cytotoxicity.” Furthermore, NK cells can also be an important source of cytokines (e.g., INF- γ , TNF- α , and *granulocyte-macrophage colony-stimulating factor* [GM-CSF]) early in the immune response.

$\gamma\delta$ T cells constitute only 0.5% to 10% of the peripheral blood lymphocyte population in humans.²⁵ However, they represent an enriched T-cell population in the pulmonary epithelium, intestinal epithelium, and skin. Unlike $\alpha\beta$ T cells, epithelial $\gamma\delta$ T cells do not recirculate and appear to represent resident pulmonary lymphocytes. The population of $\gamma\delta$ T cells in the lung of normal adult C57BL/6 mice is approximately 2 to 5×10^4 cells, with the majority being either V γ 4⁺ or V γ 1⁺.¹⁰⁹ Importantly, the different $\gamma\delta$ T-cell subsets are thought to have different functional capabilities. For example, in a murine model of asthma, V γ 1⁺ $\gamma\delta$ T cells enhance airway hyperresponsiveness, whereas V γ 4⁺ $\gamma\delta$ T cells suppress this response.¹¹⁰ The pulmonary $\gamma\delta$ T cells preferentially interact with F4/80⁺ macrophages and MHC class II-expressing dendritic cells, suggesting that

$\gamma\delta$ T cells represent a primitive line of defense evolved to protect epithelial integrity and provide a possible bridge between innate immunity and acquired immune responses. $\gamma\delta$ T cells have also been implicated in the regulation of various immune responses in the lung through IL-22 expression.¹¹¹

The distribution and trafficking of lymphocytes is governed by interactions between molecules on the lymphocyte surface and ligands present on vascular endothelial cells. The migration of lymphocytes from the bloodstream is not a random event, and this migration appears to be restricted to lymphoid tissue and areas of inflammation.⁸ Naive T cells lack the ability to initiate an antigenic response until they are activated within a secondary lymphoid organ. Evidence indicates that their initial interaction with an antigen entering through the lung takes place in the surrounding lymphoid tissues and not in the lung directly. Naive and resting lymphocytes represent the major population that recirculates from blood to lymph via HEVs,¹¹² with the initial attachment mediated by the homing receptor L-selectin (CD62L) to peripheral lymph node addressin and glycosylation-dependent cell adhesion molecule-1 on the surface of endothelial cells.⁸ This interaction results in lymphocyte tethering and rolling along the endothelial surface. Subsequent binding of chemokines (e.g., stromal cell-derived factor-1 α , 6-C-kine, and macrophage inflammatory protein-3b) to G protein-coupled receptors on the lymphocyte surface leads to activation of integrin molecules (lymphocyte function-associated antigen-1).⁸ After activation, lymphocyte function-associated antigen-1 binds to intercellular adhesion molecule-1 on the vascular endothelium, resulting in firm adhesion.⁸ This is followed by transendothelial migration of the lymphocyte into the lymphoid tissue. A second family of G protein-coupled receptors, known as sphingosine-1-phosphate receptor-1, is required for lymphocyte egress from the lymph node.¹¹³ As stated earlier, BALT consists of diffuse lymphoid aggregates found in the bronchial mucosa of most mammals.¹⁰⁶ In contrast to HEVs in other secondary lymphoid organs, BALT HEVs express high levels of vascular cell adhesion molecule-1, which binds $\alpha_4\beta_1$ integrin on T cells. Thus an adhesion cascade exists involving L-selectin/peripheral lymph node addressin, $\alpha_4\beta_1$ integrin/vascular cell adhesion molecule-1, and lymphocyte function-associated antigen-1/intercellular adhesion molecule-1, which targets specific lymphocyte populations to BALT and other bronchopulmonary tissues.^{8,106}

Effector and memory T lymphocytes appear to have distinct pathways of lymphocyte recirculation compared with naive lymphocytes.⁸ Effector T cells, especially after activation in the lymphoid tissues, travel to regions of inflammation where chemokines and other chemotactic molecules are generated by the underlying inflammatory process.⁸ Expression of various adhesion molecules on the lymphocyte and binding to their appropriate molecular targets expressed on inflamed vascular endothelium allow cells to enter sites of inflammation.⁸ The expression of intercellular adhesion molecule-1, P-selectin, and vascular cell adhesion molecule-1 on the surface of inflamed vascular endothelium is involved in lymphocyte entry into areas of inflammation.⁸ Tissue tropism is established by the expression of different combinations of adhesion molecules that allow a

different subset of effector cells to home to different sites. For example, circulating memory lymphocytes specific for skin-associated antigens express the cutaneous lymphocyte antigen.⁸ Conversely, memory for intestinal antigens has been localized to circulating lymphocytes expressing high levels of $\alpha_4\beta_7$ integrin.⁸ Thus memory T cells display selective homing to the tissue type where antigen was first encountered.

ANTIBODY-MEDIATED IMMUNE RESPONSES IN THE LUNG

Immune Response to Extracellular Pathogens

The humoral immune response is adapted for elimination of extracellular pathogens. An example of an antibody-mediated immune response is that which takes place after exposure to *Streptococcus pneumoniae*. This bacterium frequently colonizes the nasopharynx and is the most common cause of community-acquired pneumonia.¹¹⁴ Pneumococci gain access to the lower respiratory tract via aspiration. The upper airway is equipped with clearance mechanisms (e.g., mucociliary clearance and cough) that effectively eliminate most inhaled or aspirated bacteria from the airways (see Chapter 11). If the aspirated pneumococcus evades the upper airway defenses, the pathogen first encounters the mucosal humoral immune system. IgA provides the first line of defense against infectious agents, with IgG and IgM being less important in the bronchial secretions. The major functions of secretory IgA include the prevention of microbial adherence to the epithelial surface and the promotion of the agglutination of microorganisms. The combination of inhibition of adhesion and microbial agglutination favors the clearance of pneumococci via mechanical forces. Unlike IgG, IgA is unable to activate complement and is not an effective opsonin.

The first exposure of the host to the pneumococcus generates a primary humoral response. Bacteria in the lung are bound by antigen-presenting cells, which migrate to secondary lymphoid organs, where antigens are processed and presented with class II MHC molecules to CD4⁺ T cells (Fig. 13-11). After TCR binding and effective co-stimulation enhanced by an inflammatory environment, specific T cells are activated and multiple T helper cytokines are elaborated. During this process, naive B cells in the lymph node bind unprocessed antigen via surface IgM and present peptide fragments to specific T helper cells via class II MHC molecules. T-cell–B-cell interactions in the germinal centers lead to additional T-cell and full B-cell activation, characterized by clonal proliferation, isotype switching, and differentiation of B cells into secreting cells and memory cells. Subsequently, specific antibody, activated T cells, and perhaps some activated B cells circulate back to the lung to combat the pneumococcal infection.

In the area of infection, IgG1, IgG3, and IgM specific for intact pneumococcal antigens activate the complement system, resulting in some bacterial cell lysis. More important, antibody and complement act as opsonins, enhancing phagocytosis of encapsulated microorganisms. The release of mediators from activated T cells also enhances the antibacterial capacity of recruited nonspecific inflammatory cells in the lung. These events take place over a 4- to 7-day

Figure 13-11 Immune responses in the lung. Antigen (e.g., bacterial pathogen) enters the lung. Microbial products create an inflammatory environment. **1**, Antigen is taken up by nonspecific phagocytic cells and transported to regional lymph nodes. **2**, In the lymph nodes a primary immune response is generated. Antigen-specific T cells are stimulated, and initial T helper cell–B-cell interactions and antibody production take place in the germinal centers. **3**, Antibodies, T helper cells, and effector cells circulate back to the lung for the immune response to target the pathogen. Trafficking of inflammatory cells is enhanced by the production of chemokines and other chemotactic factors and involves interactions of leukocytes with endothelial cells in the area of inflammation. In the process of the initial immune response, memory T cells and B cells are generated. This allows for the generation of a more effective secondary immune response if the same pathogen is encountered at a later time.

period and characterize the initial phase of a primary response. The time needed for peak response is approximately 7 to 10 days. The presence of memory B and T cells ensures that repeat exposure to *S. pneumoniae* results in a secondary immune response, which is characterized by a shorter lag phase, resulting in a more rapid response of greater magnitude and longer duration. Clinically, pneumococcal vaccination, which induces a primary humoral response, has decreased the rates of invasive pneumococcal disease in both children and adults.¹¹⁵

Immune Response to Autoantigens

Autoimmune disorders result when the normal mechanisms of immune self-tolerance fail. Essentially all autoimmune diseases, including antibody-mediated autoimmune diseases, appear to be dependent on the inappropriate activation of autoreactive CD4⁺ T cells as well as on the autoreactive B cells responsible for the pathogenic autoantibodies. One example of an autoimmune disease involving the lung is Goodpasture syndrome. This syndrome is characterized by pulmonary hemorrhage and glomerulonephritis, which are associated with elevated levels of IgG antibodies directed against basement membrane antigens. In various studies, pathologic damage has been shown to be dependent on the binding of these autoantibodies, which are primarily directed against the noncollagenous domain ($\alpha 3$ chain) of type IV collagen in basement membrane.¹¹⁶⁻¹¹⁸ Immunofluorescent staining with anti-human IgG antibodies usually reveals a linear deposition of IgG in the glomerular and alveolar basement membranes. Despite the widespread distribution of type IV collagen in the body, disease expression is mostly limited to the lungs and kidneys. This limited disease expression suggests the possibility that other factors

allow exposure of this autoantigen selectively in alveolar or glomerular basement membranes. In this regard, influenza A2 infection, hydrocarbon inhalation, and cigarette smoking have been associated with the initial episode of diffuse alveolar hemorrhage and exacerbation of disease in the setting of elevated levels of anti-basement membrane antibodies.¹¹⁹ Much is now known regarding how autoantibodies cause damage in an autoimmune disease such as Goodpasture syndrome. More recently, HLA associations and the B- and T-cell epitope have been identified.¹²⁰ *HLA-DRB1*15:01* is strongly associated with the development of Goodpasture syndrome, whereas *HLA-DRB1*07:01* and *DRB1*01:01* confer protection against development of this disease. In addition, the T-cell epitope has been mapped to the amino-terminal region of the $\alpha 3$ chain of type IV collagen.¹²¹ As noted earlier, activation of both autoreactive CD4⁺ T cells and autoreactive B cells appears to be necessary for a pathologic autoimmune response. These autoreactive CD4⁺ T cells require CD28 co-stimulation, because blockade of this co-stimulatory molecule reduces anti-basement membrane antibody production and prevents the development of experimental autoimmune glomerulonephritis.¹²²

Studies have identified an autoimmune cause underlying the development of acquired pulmonary alveolar proteinosis.¹²³ This disorder is characterized by the accumulation of a periodic acid–Schiff staining, granular, eosinophilic material within the alveolar space (see Chapter 70). Based on the development of pulmonary alveolar proteinosis in mice rendered deficient in GM-CSF, a fundamental role of this factor in surfactant homeostasis has been discovered.¹²⁴ In addition, the presence of neutralizing IgG autoantibodies directed against GM-CSF have been identified in the bronchoalveolar lavage fluid and serum of all patients with acquired pulmonary alveolar proteinosis, but not in individuals with the congenital or secondary form of the disorder or in normal control subjects.¹²⁵ The detection of this IgG autoantibody is highly sensitive and specific and thus useful in the diagnosis of the acquired form of this disease. More recently, mutations in the ligand-binding α chain of the GM-CSF receptor have been identified in pediatric patients with pulmonary alveolar proteinosis.¹²⁶

Immune Response in Allergic Disease

Atopic asthma results when an immune response and IgE antibodies are directed against normally harmless proteins present in the environment (see Chapter 41). Numerous cell types, including mast cells, eosinophils, macrophages, and CD4⁺ T lymphocytes, as well as the specific IgE-secreting B cells, are important in the development of allergy and asthma. The CD4⁺ T cells, which accumulate in the lungs of asthmatics, display a Th2 phenotype,¹²⁷ and studies using murine asthma models have shown that allergic airway inflammation is dependent on Th2-type CD4⁺ T cells. As discussed earlier, the development of a Th2 response is prompted by exposure of naive CD4⁺ T cells to IL-4 at the beginning of an immune response.^{56,57,87,89} In the presence of high expression of IL-4 and low IFN- γ , these Th2 CD4⁺ T cells induce isotype switching in antigen-specific B cells to IgE.¹²⁸ The elevated levels of IgE in the asthmatic are essential for the immediate hypersensitivity response. The presence of IL-4 and IL-5 and the production of various chemokines during T-cell activation also enhance accumu-

lation of eosinophils and basophils in the airways. Studies in murine models of allergic asthma have suggested an important role for another Th2 cytokine, IL-13, which was capable of inducing the pathologic features of asthma independent of IgE and eosinophils.¹²⁹ Related to the Th2 dependence of asthma in humans, susceptibility to disease has been linked to loci on chromosome 5q, which contains the genes for IL-4 and IL-13.¹³⁰ Studies also suggest that genetically determined abnormalities in antigen-presenting cells may also play a role in the development of allergic reactions. In atopic individuals, antigen-presenting cells were shown to underproduce IL-12 or overproduce prostaglandin E₂, which favors a Th2 response.¹³¹

CELL-MEDIATED INFLAMMATORY RESPONSES IN THE LUNG

Cell-mediated immune responses can be divided into two major categories: (1) CD4⁺ T cells that mediate delayed-type hypersensitivity reactions and (2) CD4⁺ T cells that help effector T cells with cytotoxic function.

Granulomatous Lung Disease

Granulomas are characteristic of infections that live at least partly intracellularly, such as *Mycobacterium tuberculosis*, *Mycobacterium leprae*, and organisms that are large and persistent. There is considerable evidence to suggest that CD4⁺ T cells and the elaboration of Th1 cytokines are required for maximal granulomatous inflammation in the response to these infections. The triggering event in the development of noninfectious granulomatous lung disease is the deposition of antigen in the lung parenchyma. In the case of chronic beryllium disease^{67,132} and hypersensitivity pneumonitis (see Chapter 64), the antigenic stimulus is known. In sarcoidosis, the inciting agent is unknown, although the immunopathogenic events are believed to be the same (see Chapter 66).¹³³ Thus the unknown antigen is likely to be engulfed by antigen-presenting cells (i.e., dendritic cells and macrophages) in the lung parenchyma and presented to naive CD4⁺ T cells in the peripheral lymphoid organs. In the absence of IL-4, exposure of these activated naive CD4⁺ T cells to IL-12 released by macrophages directs the T cell toward a Th1 response.^{56,57,87,89} The development of a Th1 response is also influenced by early release of IFN- γ through the up-regulation of IL-12 production by macrophages and through the up-regulation of receptors for this cytokine on Th1 cells.

Production of chemokines and other chemotactic factors at the site of inflammation in the lung directs migration of activated effector CD4⁺ T cells to the lung. The Th1 cytokines and other mediators produced by these T cells are responsible for the recruitment and activation of macrophages and other nonspecific inflammatory cells. The accumulation of inflammatory cells within the alveolus (alveolitis) appears to be the initial lesion characterizing sarcoidosis and other granulomatous lung diseases. In sarcoidosis the accumulated CD4⁺ T cells (obtained at bronchoalveolar lavage) include expanded subsets, identified by expression of particular TCR V β and V α regions. Within these subsets are expansions of T-cell clones, each with a unique TCR β chain and α chain sequence. The presence of these oligoclonal expansions indicates a T-cell response to

conventional peptide antigens, and the presence of different T-cell clones with related TCRs indicates a response to the same antigen. Both the HLA haplotype (the presenting class II MHC molecule) in an individual and the stimulating antigen(s) will determine the TCRs used in these T-cell responses. In chronic beryllium disease, particular HLA-DP alleles (e.g., *HLA-DPB1* alleles expressing a glutamic acid residue at the 69th position of the β -chain) appear to be most important in the presentation of antigen to beryllium-specific T cells,¹³⁴ and this likely explains the increased disease susceptibility in individuals with the same HLA-DP alleles.¹³⁵ CD4⁺ T-cell clones expressing similar TCRs (with the same V regions and highly similar CDR3 regions) have been noted to be expanded in the lungs of different individuals with chronic beryllium disease, reflecting similarities in presenting MHC class II molecules and the same stimulating antigen (beryllium).¹³¹ In sarcoidosis an association between the TCR usage of V α 2.3 and HLA-DR17 (DR3) expression has been reported.¹³⁶ It is important to emphasize that the pathologic T-cell responses in these diseases are compartmentalized to the lung, because the same T-cell clones are either absent or rare in the peripheral blood.¹⁰⁵

The major effector cells of inflammation in chronic beryllium disease, sarcoidosis, and other granulomatous diseases appear to be macrophages primarily derived from circulating monocytes during the process of inflammation. Activated alveolar macrophages express MHC class II molecules and may contribute to antigen presentation. Noncaseating granulomas form by coalescence of activated macrophages, which can also fuse to form multinucleated giant cells. CD4⁺ T cells predominate in the center of the noncaseating granuloma, with CD8⁺ T cells located at the periphery of the granulomatous response.

CYTOTOXIC T-CELL REACTIONS IN THE LUNG

Cytotoxic T lymphocytes (CTLs) are critical in the recognition and elimination of virus-infected cells and tumor cells as well as in allograft rejection. These cells predominantly express CD8, although CD4⁺ CTLs and NK cells may also be involved in cytotoxic T-cell responses. CD4⁺ T helper cells are almost always required for full expression of a cytotoxic T-cell reaction. CTL responses have been detected in humans after infection with numerous viruses, including respiratory syncytial virus, parainfluenza, and influenza A and B. Once a CD8⁺ CTL recognizes a respiratory syncytial virus-infected cell, there are at least three distinct mechanisms by which the CTL can induce cell death.⁹⁹⁻¹⁰² As discussed earlier, CTLs can secrete cytotoxic cytokines such as TNF- α and IFN- γ in the vicinity of the target cell. In addition, CTLs can release granule enzymes, including perforins and granzymes, which cause pore formation in the membrane of the target cell and enzyme-mediated apoptosis. Finally, CTLs can induce cell death via the interaction of FAS ligand on its surface with FAS on the target cell. CD4⁺ CTLs do not have cytotoxic granules and primarily use FAS-mediated apoptosis as their mechanism of cytotoxicity.

NK cells have a role complementary to that of CTLs in combating virus-infected cells or tumor cells.⁷ NK cells appear to form the first line of defense against viral infection, providing nonspecific cytotoxic activity. These cells

differ from CTLs in their lack of TCRs, and they recognize their targets in a non-MHC-restricted fashion. However, the mechanism of NK cell killing appears to be similar to that employed by CD8⁺ CTLs. In addition, NK cells have receptors for IgG (FCGR3; CD16) and can bind to the Fc region of antibody attached to the surface of a target cell and mediate antibody-dependent cellular cytotoxicity.

Key Points

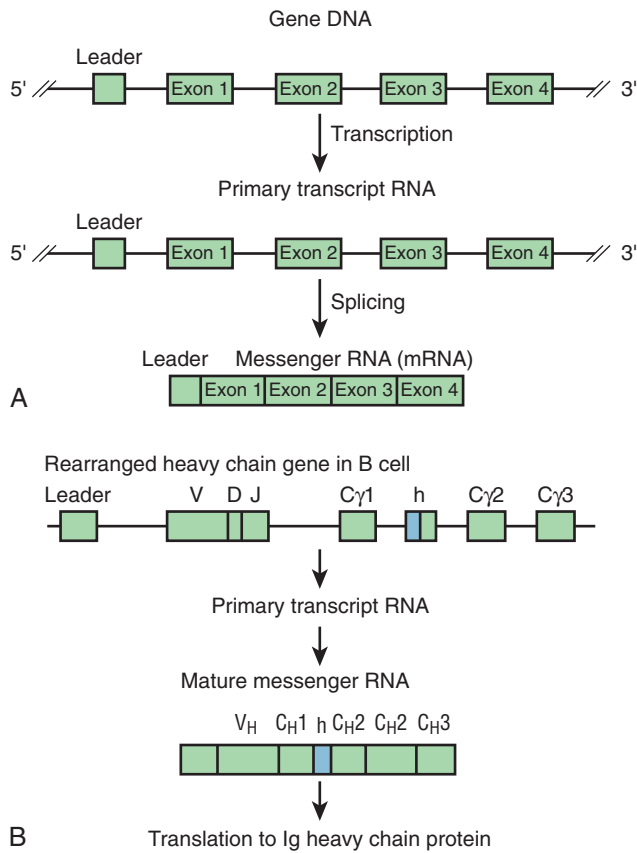

- The health of the lung and the individual depends on a functional immune system to protect against microbial invasion.
- Pathogens are targeted by both specific humoral immune responses and a variety of cell-mediated responses that result in activation and accumulation of leukocytes.
- Although effector leukocytes may be both antigen specific and antigen nonspecific, essentially all of these immune responses are dependent on specific T (helper) cells for full expression and maximal effect.
- The vast array of pathogens and their large number of strategies to subvert the immune system is combated by a system of defense with remarkable specificity and yet enormous diversity. These capabilities are achieved through unique molecular mechanisms of the B-cell receptor and the T-cell receptor repertoire formation, which are fundamental to understanding the adaptive immune response.
- The regulation of specific immune responses is dependent on cytokine expression and cellular interactions of various regulatory T cells with effector T-cell subsets.
- In occasional individuals, the defense system may break down and, in others, aberrant immune responses appear to contribute to various pathologic conditions relevant to the lung and respiratory tract.
- Granulomatous lung diseases (e.g., sarcoidosis and chronic beryllium disease) are characterized by an excessive type 1 T helper CD4⁺ T-cell response, whereas allergic diseases (e.g., asthma) are characterized by excessive type 2 T helper responses.
- Type 17 T helper polarized immune responses are typically seen in bacterial pneumonia and in subjects with severe, corticosteroid-unresponsive asthma.
- Additional knowledge of the structure and function of the immune system will likely provide new insight into lung disease development and lead to new therapeutic approaches.

eFIGURE IMAGE GALLERY

eFigure 13-1 Genes encoding immunoglobulin molecules. A, Characteristic structure of genes encoding a membrane protein. Note that the exons code for discrete structural regions of the protein, for example, an external domain, a transmembrane region, and a cytoplasmic tail. **B,** Corresponding structure of a rearranged immunoglobulin (Ig)G heavy chain gene. The leader–V region segment of DNA was initially located upstream on the same chromosome and has rearranged proximal to the DJ segment, which is proximal to the IgG C γ exons. Processing of the primary transcript brings all of the coding regions together in the messenger RNA molecule for translation of the protein. (Adapted from *MKSAP in the specialty of rheumatology*, Philadelphia, 1993, American College of Physicians, p 7.)

eFigure 13-2 B-cell development. Antigen-independent differentiation of the B cell in the adult bone marrow is shown from left to right. Pro-B and early pre-B stages involve the rearrangement of immunoglobulin (Ig) heavy chain D-J and V-DJ gene segments and transient expression of a pre-B-cell receptor (BCR). Subsequent rearrangement of immunoglobulin (Ig) light chain genes in the later pre-B cell allows for the development of a BCR-expressing immature B cell. The interaction of the mature naive B cell with antigen in the germinal centers of peripheral lymphoid organs and in the presence of T-cell help allows for somatic mutation of the Ig genes (affinity maturation), isotype switching, generation of B cells that are capable of high-rate IgG secretion, and generation of memory B cells.

eFigure 13-3 Rearrangement of genes encoding the T-cell receptor (TCR). **A,** In the germline TCR α chain gene complex, before any rearrangement in T cells, approximately 40 to 50 V α gene segments are located upstream of the multiple J α and C α gene segments. Within the TCR α chain locus is the TCR δ gene complex (expressed in $\gamma\delta$ T cells), which is deleted when V α genes are rearranged. During T-cell development, V α genes are rearranged to downstream J α gene segments to form a functional α chain gene. This process is similar to that described for immunoglobulin gene rearrangements. Expression of RNA and RNA processing allows for generation of TCR α chain messenger RNA (mRNA). **B,** A similar process allows for rearrangement of TCR β chain genes in the pre-T cell during T-cell development. In both **A** and **B**, nucleotide additions and deletions at the margins of the rearranging segments are not shown.

eFigure 13-4 T-cell development and maturation in the thymus. The rearrangement of the TCR β chain genes in the pre-T cell and then TCR α chain genes results in generation of a remarkably diverse TCR repertoire, expressed at the stage of the major immature thymocyte. These cells express TCR at relatively low density and are double positive for both CD4 and CD8. The repertoire is positively selected for (low) affinity to self-major histocompatibility complex (MHC) (self-MHC restriction). Cells with TCR that do not undergo positive selection die in the thymus by apoptosis. Immature and mature thymocytes with high affinity for self-MHC/peptide complexes are negatively selected and undergo apoptosis (deleted). Overall, greater than 95% of immature thymocytes fail to mature for export to the peripheral lymphoid organs. As immature thymocytes mature, they maintain CD4 expression and down-regulate CD8 (MHC class II restricted) or maintain CD8 expression and down-regulate CD4 (MHC class I restricted).

INTERSTITIAL LUNG DISEASES

Idiopathic Interstitial Pneumonias
Other Interstitial Lung Disease

INTRODUCTION

This chapter focuses on three areas that have received considerable interest recently. The first is the use of small biopsies and cytology, which are used not only for tissue diagnosis but also for molecular studies in lung cancer. The second is the classification of lung tumors, which has changed considerably based on several consensus conferences. This includes more precise classification of lung adenocarcinomas, which frequently have a mixture of subtypes. This is important for diagnosis, predicted outcome, and therapy. The third area is the field of *interstitial lung disease* (ILD), which now has a firm foundation for clinical studies and evaluating new therapies. These are areas which have seen considerable advances in the past 5 years. Topics such as the pathology of asthma, chronic obstructive pulmonary disease, pneumonia, and infectious disease are addressed in other chapters of this book and in the key references.

LUNG CANCER

Lung cancer is the most common cause of major cancer incidence and mortality worldwide in men, while in women

it is the third most common cause of cancer incidence and the second most common cause of cancer mortality.¹ In 2013, the American Cancer Society estimated that lung cancer would account for more than 228,190 new cases in the United States and 159,480 cancer deaths.²

The pathologic diagnosis of lung cancer is established either by a histologic or cytologic approach.³⁻⁶ Major changes in the diagnosis of lung cancer were recommended by the 2011 *International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society* (IASLC/ATS/ERS) International Multidisciplinary Classification of Lung Adenocarcinoma^{5,7} (Table 14-1). Changes have been made in the diagnostic approach to small biopsies and cytologies as well as to resection specimens (eTable 14-1).^{4,5,7} This is of great importance because 70% of lung cancer patients present with advanced stage disease and the diagnosis is based on small specimens. There are four major histologic types of lung cancer including squamous cell carcinoma, adenocarcinoma, small cell carcinoma, and large cell carcinoma.⁶ These major types can be classified into more specific subtypes such as the lepidic predominant subtype of adenocarcinoma or the basaloid variant of squamous cell carcinoma.^{4,5,7,7a}

VASCULITIS

Granulomatosis with Polyangiitis

PULMONARY HYPERTENSION**eTable 14-1** Proposed IASLC/ATS/ERS Classification for Small Biopsies/Cytology

2004 WHO Classification	Small Biopsy/Cytology: IASLC/ATS/ERS
ADENOCARCINOMA	<i>Morphologic adenocarcinoma patterns clearly present:</i> Adenocarcinoma, describe identifiable patterns present (including micropapillary pattern not included in 2004 WHO classification) <i>If pure lepidic growth—mention an invasive component cannot be excluded in this small specimen.</i> <i>Morphologic adenocarcinoma patterns not present (supported by special stains):</i> Non–small cell carcinoma, favor adenocarcinoma Adenocarcinoma with lepidic pattern (if pure, add note: an invasive component cannot be excluded) Mucinous adenocarcinoma (describe patterns present) Adenocarcinoma with fetal pattern Adenocarcinoma with colloid pattern Adenocarcinoma with (describe patterns present) and signet ring features Adenocarcinoma with (describe patterns present) and clear cell features
Mixed subtype Acinar Papillary Solid No 2004 WHO counterpart—most will be solid adenocarcinomas Bronchioloalveolar carcinoma (nonmucinous) Bronchioloalveolar carcinoma (mucinous) Fetal Mucinous (colloid) Signet ring Clear cell	
SQUAMOUS CELL CARCINOMA	<i>Morphologic squamous cell patterns clearly present:</i> Squamous cell carcinoma
Papillary Clear cell Small cell Basaloid No 2004 WHO counterpart	<i>Morphologic squamous cell patterns not present (supported by stains):</i> Non–small cell carcinoma, favor squamous cell carcinoma
SMALL CELL CARCINOMA	Small cell carcinoma
LARGE CELL CARCINOMA	Non–small cell carcinoma, not otherwise specified (NOS)
Large cell neuroendocrine carcinoma (LCNEC)	Non–small cell carcinoma with neuroendocrine (NE) morphology (positive NE markers), possible LCNEC
Large cell carcinoma with NE morphology (LCNEM)	Non–small cell carcinoma with NE morphology (negative NE markers)—see comment Comment: This is a non–small cell carcinoma where LCNEC is suspected, but stains failed to demonstrate NE differentiation.
ADENOSQUAMOUS CARCINOMA	<i>Morphologic squamous cell and adenocarcinoma patterns present:</i> Non–small cell carcinoma, NOS, (comment that glandular and squamous components are present) Comment: This could represent adenosquamous carcinoma.
No counterpart in 2004 WHO classification	<i>Morphologic squamous cell or adenocarcinoma patterns not present but immunostains favor separate favor glandular and adenocarcinoma component</i> Non–small cell carcinoma, NOS, (specify the results of the immunohistochemical stains and the interpretation) Comment: This could represent adenosquamous carcinoma.
SARCOMATOID CARCINOMA	Poorly differentiated NSCLC with spindle and/or giant cell carcinoma (mention if adenocarcinoma or squamous carcinoma are present)

- Spindle cell carcinoma
- Giant cell carcinoma
- Carcinosarcoma
- Pulmonary blastoma
- Other

Other and unclassified carcinomas

- Lymphoepithelioma-like carcinoma
- NUT carcinoma
- Unclassified carcinoma

Carcinomas of Salivary Gland Type

- Mucoepidermoid carcinoma
- Adenoid cystic carcinoma
- Epimyoeplithelial carcinoma

This classification primarily addresses histology in resected specimens. Modified from Travis WD, Brambilla E, Noguchi M, et al: Diagnosis of lung adenocarcinoma in resected specimens: implications of the 2011 International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society Lung Classification. *Arch Pathol Lab Med* 137:685–705, 2013; and Travis WD, Brambilla E, Müller-Hermelink HK, Harris CC: Pathology and genetics: tumours of the lung, pleura, thymus and heart. Lyon, 2004, IARC.

BAC, bronchioloalveolar carcinoma; NUT, nuclear protein in testis.

Historically the most important distinction was between *small cell lung carcinoma* (SCLC) and *non-small cell lung carcinoma* (NSCLC)⁶ due to significant differences in clinical presentation, spread of tumor, and response to therapy. However, over the past decade, major changes in the approach to diagnosis and treatment of NSCLC have led to a greater need for more precise classification based on small biopsies and cytology.^{4,5,7} Several therapeutic advances have provided the need for pathologists to classify tumors more precisely because the choice of therapies and decision to perform molecular testing is based on histology. Molecular testing for *epidermal growth factor receptor* (EGFR) mutations and *activin receptor-like kinase* (ALK) rearrangements is recommended for patients with adenocarcinomas, “NSCLC, favor adenocarcinoma,” and *NSCLC-not otherwise specified* (NSCLC-NOS). Patients with an EGFR mutation are eligible for EGFR tyrosine kinase inhibitors and those with *echinoderm microtubule-associated protein-like 4* (EML4)-ALK rearrangements are eligible for crizotinib therapy.⁸⁻¹² If neither EGFR mutations nor ALK rearrangements are present, patients are eligible for either pemetrexed or bevacizumab-based regimens.⁸⁻¹² However, patients with squamous cell carcinoma are not eligible for these therapies. These advances have transformed the lung cancer field and resulted in multiple paradigm shifts in the clinical practice for all specialists, including pathologists. For additional information on lung cancer, see Chapters 51, 52, and 53.

ADENOCARCINOMA

Adenocarcinomas represent 36% of all lung cancers in the United States.¹³ The 2011 IASLC/ATS/ERS lung adenocarcinoma classification recommended multiple major changes (see Table 14-1).^{4,5,14} First, it is recommended to discontinue the use of the term *bronchioloalveolar carcinoma* (BAC) because the tumors formerly classified under this term are now classified as five different tumors. Second, there are new concepts of *adenocarcinoma in situ* (AIS) (see [Preinvasive Lesions](#)) and *minimally invasive adenocarcinoma* (MIA). Third, it is recommended to stop using the term “mixed subtype” and to use comprehensive histologic subtyping to estimate the percentage of histologic patterns in 5% increments within a tumor with the final classification according to the predominant subtype. Fourth, tumors with a predominant component formerly called “nonmucinous BAC” should be classified as *lepidic-predominant adenocarcinoma* (LPA). *Lepidic* refers to the noninvasive growth of tumor cells along the surface of the air spaces. Fifth, micropapillary adenocarcinoma is recognized as a new subtype with a poor prognosis. Sixth, *invasive mucinous adenocarcinoma* is the term recommended for those tumors formerly classified as mucinous BAC. Finally, specific terminology and diagnostic criteria are proposed for tumors in small biopsies and cytology specimens along with recommendations for strategic management of tissue and EGFR mutation testing in patients with advanced adenocarcinoma.^{4,5,14}

Adenocarcinoma Classification in Resected Specimens

Invasive Adenocarcinoma. Classification of overtly invasive adenocarcinomas is now made according to the predominant subtype.^{5,14} This is best determined using

Figure 14-1 Major histologic patterns of invasive adenocarcinoma. **A**, Lepidic predominant pattern with mostly lepidic growth (left) and an area of invasive acinar adenocarcinoma (right). (H&E stain; original magnification $\times 100$.) **B**, Lepidic pattern consists of a proliferation of type II pneumocytes and club cells along the surface of the alveolar walls. (H&E stain; original magnification $\times 200$.) **C**, Area of invasive acinar adenocarcinoma (same tumor as in **A** and **B**). (H&E stain; original magnification $\times 400$.) **D**, Acinar adenocarcinoma composed of round to oval shaped malignant glands invading a fibrous stroma. (H&E stain; original magnification $\times 200$.) **E**, Papillary adenocarcinoma consists of malignant cuboidal to columnar tumor cells growing on the surface of fibrovascular cores. (H&E stain; original magnification $\times 100$.) **F**, Micropapillary adenocarcinoma consists of small papillary clusters of glandular cells growing within this airspace, most of which do not show fibrovascular cores. (H&E stain; original magnification $\times 200$.) **G**, Solid adenocarcinoma with mucin consisting of sheets of tumor cells with abundant cytoplasm and mostly vesicular nuclei with several conspicuous nucleoli. No acinar, papillary, or lepidic patterns are seen. (H&E stain; original magnification $\times 400$.) **H**, Solid adenocarcinoma with mucin. Numerous intracytoplasmic droplets of mucin (dark pink) are highlighted with this mucicarmine stain. (H&E stain; original magnification $\times 400$.)

comprehensive histologic subtyping to estimate the percentages of the various histologic subtypes within a tumor in a semiquantitative fashion in 5% to 10% increments. LPA consists of tumors formerly classified as mixed subtype tumors containing a predominant lepidic growth pattern of type II pneumocytes and/or club cells (Clara) (formerly known as nonmucinous BAC) that have an invasive component greater than 5 mm (Fig. 14-1A-C). The other major subtypes include acinar (see Fig. 14-1D), papillary (see Fig. 14-1E), micropapillary (see Fig. 14-1F), and solid with mucin-predominant adenocarcinomas (see Figs. 14-1G-H). The micropapillary-predominant subtype is a new addition due to the observation in multiple studies that it is associated with poor prognosis in early stage adenocarcinomas.^{5,14-20} It has been proposed that a cribriform pattern is associated with poor prognosis and, if this finding is validated, it may be added as a poor prognostic subtype of lung adenocarcinoma.²¹ Signet ring and clear cell carcinoma

subtypes are no longer regarded as histologic subtypes, but they are now documented as cytologic features whenever present with a comment about the percentage identified. Although clear and signet ring cell cytologic changes are seen mostly in the solid subtype, they can also be seen in acinar or papillary patterns as well.^{5,14} There is a high correlation between the appearance on *computed tomography* (CT) and the pathology features on biopsy; the ground-glass component on CT tends to correlate with lepidic growth on biopsy, whereas the solid component on CT tends to correlate with invasive components on biopsy.^{22,23}

Adenocarcinoma Variants. Lung adenocarcinoma can consist of several variants including invasive mucinous adenocarcinoma (formerly mucinous BAC), colloid adenocarcinoma, fetal adenocarcinoma, and enteric adenocarcinoma.^{5,14} Invasive mucinous adenocarcinomas (formerly mucinous BAC) differ from the nonmucinous invasive

Figure 14-2 Invasive mucinous adenocarcinoma. This area of invasive mucinous adenocarcinoma demonstrates a pure lepidic growth. The tumor consists of columnar cells filled with abundant mucin in the apical cytoplasm and shows small basal oriented nuclei. (H&E stain; original magnification $\times 200$.)

adenocarcinomas due to the frequent association with *KRAS* mutations, lack of *thyroid transcription factor-1* (TTF-1), and frequent presentation with multicentric lung involvement. While historically, the lepidic pattern has been emphasized with these tumors, sometimes it is not present, and these tumors show varying amounts of other invasive patterns including acinar, papillary, or micropapillary growth. The characteristic histologic features consist of the tumor cell morphology of columnar cells with abundant apical mucin and small basally oriented nuclei (Fig. 14-2).^{5,14} By CT, these tumors typically show localized or multifocal consolidation with air bronchograms, forming nodules and/or lobar consolidation.

PROGNOSIS OF ADENOCARCINOMA SUBTYPES IN RESECTED SPECIMENS. A growing number of studies have evaluated prognosis of the adenocarcinoma subtypes according to the precise criteria and terminology of the new classification.^{15-19,24-29} Yoshizawa and colleagues¹⁶ identified three groups of tumors with different grades of clinical behavior: (1) low-grade AIS and MIA with 100% 5-year disease-free survival, (2) intermediate grade nonmucinous lepidic predominant, papillary predominant, and acinar predominant with 90%, 83%, and 84% 5-year disease-free survival, respectively, and (3) high-grade invasive mucinous adenocarcinoma, colloid predominant, solid predominant, and micropapillary predominant with 75%, 71%, 70%, and 67% 5-year disease-free survival, respectively. Generally, similar results have been demonstrated in additional independent data sets.^{15,17-19,24-29} Studies that have failed to show prognostic significance for the concepts in the new adenocarcinoma classification have either had small numbers of patients, used overall survival rather than disease-free survival, or focused on patients with advanced disease.³⁰⁻³² Because most patients with stage I lung adenocarcinomas die of causes other than lung cancer, overall survival does not reflect the true biology of the tumor, and methods such as disease-free or recurrence-free survival are more clinically relevant.

Minimally Invasive Adenocarcinoma. MIA was introduced to describe a lepidic-predominant tumor measuring 3 cm or less that has 5 mm or less of an invasive component (Fig. 14-3).^{5,14} Limited data suggest that patients with MIA will have almost a 100% 5-year disease-free survival.^{5,14-16,33,34} Most of these are nonmucinous, but rarely some of these are mucinous cases.^{5,14-16} On chest CT, nonmucinous MIA typically shows ground-glass opacity with a solid component measuring 5 mm or less, whereas mucinous MIA typically presents as a solid nodule.^{5,14}

Preinvasive Lesions. *Atypical adenomatous hyperplasia* (AAH) was previously the only preinvasive lesion for lung adenocarcinoma but now AIS has been added.

ATYPICAL ADENOMATOUS HYPERPLASIA. AAH is an atypical pneumocyte proliferation that resembles but falls short of criteria for nonmucinous AIS (see Fig. 14-1).^{6,35-38} AAH is typically found as an incidental histologic finding in a lung cancer resection specimen.

The incidence of AAH varies from 6% to 21% depending on the extent of the search and the criteria used for the diagnosis.^{39,40} Most lesions of AAH are less than 5 mm in diameter and frequently they are multiple.^{6,35-40} Histologically, AAH consists of a focal proliferation of slightly atypical cuboidal to low columnar epithelial cells along alveoli and respiratory bronchioles (Fig. 14-4). Slight thickening of alveolar septa may be present.

AAH must be distinguished from a variety of lesions; the most important of which is the nonmucinous AIS, MIA, or lepidic-predominant adenocarcinoma.⁴ This distinction can be difficult because there is considerable overlap in the morphologic features between AAH and the lepidic pattern of adenocarcinoma. Currently, there are no data to show that patients with lung cancer and AAH have any different prognosis from those without AAH.⁴¹

ADENOCARCINOMA IN SITU. In the new IASLC/ATS/ERS adenocarcinoma classification, AIS is defined as a glandular proliferation measuring 3 cm or less that has pure lepidic growth lacking invasion (Fig. 14-5).^{5,14} In most cases the tumor cells are nonmucinous, with a proliferation of type II pneumocytes or club cells, but rarely they are mucinous, consisting of tall columnar goblet cells having abundant apical mucin. If these lesions are completely resected, patients have been reported to have 100% 5-year disease-free survival.^{5,14,42-45} On chest CT, these lesions typically consist of a ground-glass opacity if nonmucinous and a solid nodule of mucinous AIS.^{5,14,46}

TNM Staging: Potential Changes According to New Classification

Several aspects of TNM (*tumor, node, metastasis*) staging may be modified based on the 2011 lung adenocarcinoma classification.^{5,14} In the setting of multiple nodules of lung adenocarcinoma, the distinction between metastases or primary cancers that are either *synchronous* (presenting within 2 months of each other) or *metachronous* (presenting more than 2 months apart) can be helped by the use of comprehensive histologic subtyping and the analysis of other morphologic features including cytologic and stromal characteristics. These morphologic features have been shown to correlate highly with molecular and clinical outcomes.⁴⁷⁻⁴⁹ The decision to classify a second tumor as an

Figure 14-3 Nonmucinous minimally invasive adenocarcinoma. **A**, This adenocarcinoma tumor consists primarily of lepidic growth with a small (<0.5 cm) area of invasion (*bottom left*). (H&E stain; original magnification $\times 1$.) **B**, This area shows lepidic growth characterized by thickening of the alveolar walls which are lined by crowded atypical pneumocytes. **C**, From the area of invasion, these acinar glands are seen to be invading into the fibrous stroma. (H&E stain; original magnification $\times 200$.)

Figure 14-4 Atypical adenomatous hyperplasia (AAH). **A**, This millimeter-sized bronchioloalveolar proliferation is ill defined with mild thickening of the alveolar walls. (H&E stain; original magnification $\times 20$.) **B**, The alveolar walls show mild fibrous thickening and the hyperplastic pneumocytes show minimal atypia and gaps between the cells. (H&E stain; original magnification $\times 400$.)

intrapulmonary metastasis or a separate primary has a great impact on TNM staging and patient management (see Chapter 55).

In the future, tumor size for T-factor staging may be measured by invasive size rather than total size. Pathologically, comprehensive histologic subtyping can aid in determining the size of the invasive component by subtracting the percentage of the lepidic component. Several studies have shown that the invasive size is an independent prognostic factor.^{16,19,29,50} These data suggest that, like in breast cancer, the T factor for early lung adenocarcinomas may be best determined by the size of the invasive component rather than the total tumor size. On chest CT, the solid versus ground-glass component generally corresponds to the invasive versus lepidic pattern seen by histologic examination. Initial data also suggest that the size of the solid component rather than the total size including the ground-glass component is a better predictor of prognosis.⁵¹ Because CT

Figure 14-5 Nonmucinous adenocarcinoma in situ. **A**, This circumscribed nonmucinous tumor grows purely with a lepidic pattern. No foci of invasion or scarring is seen. (H&E stain $\times 4$). **B**, Higher magnification shows slight thickening of alveolar walls which are lined by crowded atypical pneumocytes. (H&E stain $\times 200$).

assessment is used for clinical staging, hopefully sufficient data can be accumulated before the next TNM revision to address this issue.

Adenocarcinoma Classification in Small Biopsies and Cytology

The IASLC/ATS/ERS lung adenocarcinoma classification provides criteria for diagnosis of lung cancer in small biopsies and cytology (see [eTable 14-1](#)).^{4,14} This is of great importance because 70% of lung cancer patients present with advanced stage disease and the diagnosis is based on small specimens. The new therapeutic implications based on histology provide the rationale for pathologists to distinguish adenocarcinoma from squamous cell carcinoma. Patients with advanced stage tumors who have the pathologic diagnosis of adenocarcinoma, NSCLC, favor adenocarcinoma, or NSCLC-NOS are eligible for three therapeutic options that are not available to patients with squamous cell cancer. Patients with adenocarcinoma may exhibit *EGFR* mutations and, if so, *EGFR* tyrosine kinase inhibitor therapy has benefit for response and progression-free survival.⁹⁻¹¹ In

addition, patients with adenocarcinoma are responsive to pemetrexed, whereas those with squamous cell carcinoma show little response.⁵² Finally, patients with adenocarcinoma may respond to the anti-vascular endothelial growth factor agent bevacizumab, whereas those with squamous cell carcinoma treated with bevacizumab have experienced life-threatening hemorrhage.⁵³ These clinically important differences between adenocarcinoma and squamous cell carcinoma make pathologic distinction essential.

In the 2011 lung adenocarcinoma classification, tumors that show clear morphologic features of adenocarcinoma or squamous cell carcinoma are classified with these standard terms. However, if the tumor only shows a carcinoma with no clear squamous or glandular features (NSCLC-NOS), a minimal immunohistochemical workup is recommended using a single adenocarcinoma marker and squamous marker, which should allow for classification of most tumors. At the moment, the best markers for adenocarcinoma and squamous cell carcinoma are TTF-1 and p63, respectively.^{4,14} In a tumor that shows no clear squamous or glandular morphology, but the staining results favor adenocarcinoma (i.e., TTF-1 positive, p63 negative), the tumor should be classified as NSCLC, favor adenocarcinoma ([Fig. 14-6](#)). Likewise, if the stains in such a tumor favor squamous cell carcinoma, the diagnosis would be NSCLC, favor squamous cell carcinoma ([Fig. 14-7](#)). Then, for tumors in which there is clear differentiation by light microscopy or special stains or if the results are conflicting, the diagnosis remains NSCLC-NOS. Cytology is another powerful tool in subclassifying poorly differentiated NSCLC.⁵⁴ In some cases, it may be easier to classify the tumor based on cytology than on biopsy.^{4,14} It is recommended to avoid use of the term “nonsquamous carcinoma” and state the specific diagnosis in precise terms as outlined earlier.^{4,14} Also, use of the term NSCLC should be minimized and instead the specific diagnosis (adenocarcinoma or squamous cell carcinoma) should be used when possible.^{4,14}

The approach to interpretation of small biopsies and cytology must include considerations of diagnoses other than NSCLC, such as neuroendocrine tumors (carcinoid, small cell carcinoma, or large cell neuroendocrine carcinoma) as well as metastatic tumors including metastatic malignant melanoma, breast cancer, or prostate cancer.^{4,14} Therefore, if the initial evaluation does not clearly point to adenocarcinoma or squamous cell carcinoma, some of these other diagnoses may need to be considered.

The diagnosis of NSCLC-NOS was encouraged by previous World Health Organization classifications when there was no clinical value in being more precise. In studies of advanced NSCLC, this diagnosis was made in 20% to 40% of cases and some data suggest its use has been increasing.^{52,55} However, with the new IASLC/ATS/ERS criteria and utilization of immunohistochemistry as well as cytology correlation, the percentage of NSCLC diagnosed as NSCLC-NOS, should be less than 5% of cases.^{4,14}

EGFR Mutation Testing

In the new IASLC/ATS/ERS Lung Adenocarcinoma Classification, there is a clinical recommendation that *EGFR* mutation testing should be performed in advanced lung adenocarcinomas because of the predictive benefit of

Figure 14-6 Non-small cell carcinoma, favor adenocarcinoma. **A**, This carcinoma shows no clear squamous or glandular differentiation. (H&E stain; original magnification $\times 200$.) **B**, The diffuse positive TTF-1 staining allows for the diagnosis of non-small cell carcinoma, favor adenocarcinoma. (H&E stain; original magnification $\times 200$.)

EGFR mutations with treatment by *EGFR* tyrosine kinase inhibitors as described earlier.^{4,14} *EGFR* mutation testing should be performed for all patients with a pathologic diagnosis of (1) adenocarcinoma, (2) NSCLC, favor adenocarcinoma, and (3) NSCLC-NOS. This recommendation has major implications for tissue management and pathologic diagnosis.

Multidisciplinary Strategy Needed to Obtain and Process Small Biopsies and Cytology

Each institution needs to develop a multidisciplinary strategy to manage these small pieces of tissue at each stage of handling: (1) obtaining the specimen, (2) processing it in the pathology laboratory, (3) providing material to the molecular diagnostic laboratory, and (4) documenting the results in a pathology report and the medical record.^{4,14} This process requires ongoing communication between

Figure 14-7 Non-small cell carcinoma, favor squamous cell carcinoma. **A**, This carcinoma shows no clear squamous or glandular differentiation. (H&E stain; original magnification $\times 200$.) **B**, The diffuse positive p63 staining and negative thyroid transcription factor 1 (TTF-1) staining (not shown) allows for the diagnosis of non-small cell carcinoma, favor squamous cell carcinoma. (Immunohistochemistry for p63; original magnification $\times 200$.)

specialists to ensure optimal management of tissues and efficient reporting of results. One of the central aspects of this process that impacts radiologists, pulmonologists, and surgeons is the need to obtain sufficient tissue not only for diagnosis, but also for molecular studies. To that end, biopsy procedures should be designed to result in either a core biopsy or a cell block from tissue samples obtained for cytology.^{4,14} Cytology specimens such as pleural fluids should also be processed to generate cell blocks such that immunostaining and molecular studies can be performed.

Use of Minimal Stains to Maximize Tissue for Molecular Testing

Pathologists should minimize the amount of tissue used for making the diagnosis, including use of as few special stains as possible.^{4,14} This is necessary to preserve as much tissue as possible for molecular testing. One helpful approach is to cut multiple unstained slides from the block after initial review in cases that are potential candidates for molecular

testing, so that the block is cut only once and valuable tissue is not lost during the process of facing the block multiple times; *facing* is the process of shaving tissue from the surface to obtain full cuts across the tissue block. This would include tumors that are either clearly adenocarcinoma or those with NSCLC-NOS patterns that will require special stains. If adenocarcinoma is suspected, a single stain for TTF-1, if positive, would confirm not only the adenocarcinoma diagnosis but also a pulmonary origin. If by morphology the tumor could be either adenocarcinoma or squamous cell carcinoma, it may be best to perform one adenocarcinoma (i.e., TTF-1) and one squamous (i.e., p63) marker as recommended in the new classification.^{4,14} Limited additional stains may be considered for the small percentage of cases that cannot be classified after this initial panel.^{4,14} Molecular testing guidelines for lung adenocarcinoma: Utility of cell blocks and concordance between fine-needle aspiration cytology and histology samples.^{55a}

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma accounts for approximately 20% of all lung cancers in the United States.¹³ Historically, two thirds of squamous cell carcinomas presented as central lung tumors, but one third were peripheral.^{56,57} However, recent reports document an increasing percentage of squamous cell carcinomas in the periphery, exceeding 50% in some studies.⁵⁸ The morphologic features that suggest squamous differentiation include intercellular bridging, squamous pearl formation, and individual cell keratinization (Fig. 14-8). In well-differentiated tumors these features are readily apparent; however, in poorly differentiated tumors, they are difficult to find.⁵⁹ Squamous cell carcinoma arises most often in segmental bronchi and involves the lobar and main-stem bronchus by extension. According to the 2004 World Health Organization classification, squamous cell carcinoma can have papillary, clear cell, small cell, and basaloid subtypes.⁶ However, this subtyping needs updating because it does not address the morphologic spectrum of appearances of lung squamous cell carcinoma, and

Figure 14-8 Squamous cell carcinoma. These tumor cells have abundant eosinophilic keratinized cytoplasm and form nests and keratin pearls (arrow) characteristic of squamous differentiation. (H&E stain; original magnification $\times 200$.)

it does not allow for meaningful correlations with clinical, prognostic, or molecular features. For example, the small cell variant probably should be dropped because most of these cases would be better classified as basaloid variants, and the term “small cell” creates confusion with true small cell carcinoma.

Several papers have proposed alternative approaches to subclassifying pulmonary squamous cell carcinomas.^{58,60,61} These include recognition of an alveolar space-filling variant, which corresponds to a favorable prognosis.^{58,61} However, this pattern is seen in the minority of cases, more often it is seen only focally and, in a study from North America, prognostic significance could not be demonstrated.⁶² In another study of pulmonary squamous cell cancer, minimal tumor cell nests were defined as large (more than six tumor cells), small (two to five cells), and single cell; the single cell infiltrating tumors had the worst prognosis.⁶⁰ Also, tumors associated with a background of *usual interstitial pneumonia* (UIP) and lymph node metastases had a poor prognosis.⁶⁰ Further work is needed to develop a more practical approach to subclassification of squamous cell carcinoma and to identify better histologic predictors of prognosis.

Squamous Dysplasia and Carcinoma In Situ

Squamous cell carcinoma develops through a multistep process in which the normal bronchial mucosa progresses through a series of lesions from basal cell hyperplasia to squamous metaplasia, dysplasia, and carcinoma in situ.^{6,35,36} In addition to the spectrum of histologic features, there is an accumulation of molecular events through the progression of increasing dysplasia to carcinoma in situ and invasive squamous cell carcinoma.³⁵

According to the severity of cytologic atypia and thickness of involvement of the bronchial mucosa, squamous dysplasia may be classified as mild, moderate, or severe.^{6,35,36} These changes represent a continuum of abnormalities; when there is marked cytologic atypia of the full thickness of the bronchial mucosa, the diagnosis is carcinoma in situ.⁶³ Dysplasia must be distinguished from reactive atypia associated with inflammation or granulation tissue. Microinvasive squamous cell carcinoma also needs to be distinguished from carcinoma in situ with involvement of submucosal glands.^{6,35,36}

NEUROENDOCRINE TUMORS

Small Cell Carcinoma

SCLC accounts for 14% of invasive lung cancers in the United States annually.¹³ Most cases present as a perihilar mass (see eFig. 53-21). Because most patients present in an advanced stage, the diagnosis is often made based on transbronchial biopsy and/or cytology, and these specimens are very reliable. SCLC may also present as a solitary coin lesion in up to 5% of cases,^{64,65} but the rarity of early stage tumors makes it unusual to encounter SCLC as a surgical specimen.

The morphology of SCLC characteristically shows tumor cells with small size, a round to fusiform shape, scant cytoplasm, finely granular nuclear chromatin, and absent or inconspicuous nucleoli (Fig. 14-9).^{6,66} Tumor cells typically

Figure 14-9 Small cell carcinoma. This tumor is composed of small cells with scant cytoplasm, finely granular chromatin, and frequent mitoses. Nucleoli are absent. (H&E stain; original magnification $\times 400$.)

grow in diffuse sheets, but may show rosettes, peripheral palisading, and organoid nesting.^{6,66,67} Mitoses are frequent, averaging 80 per 2 mm² area, and necrosis is usually extensive.^{6,66,67}

Combined SCLC. SCLC can present in combination with various types of non-small cell carcinomas in less than 10% of cases, with large cell carcinoma (Fig. 14-10) in about 4% to 6% of cases,⁶⁸ and with adenocarcinoma or squamous cell carcinoma in 1% to 3% of cases.⁶⁸⁻⁷¹ In addition, SCLC can be combined with spindle cell carcinoma,^{72,73} giant cell carcinoma,⁷³ and carcinosarcoma.⁷⁴ To date, compared with patients with pure SCLC, no significant difference has been demonstrated in clinical features, prognosis, or response to therapy.^{70,71}

A good quality hematoxylin and eosin stain is the most important stain for the diagnosis of SCLC, although immunohistochemistry is frequently used. In most tumors, a definite diagnosis can be established based on hematoxylin and eosin without immunostains. Immunohistochemistry using a pancytokeratin antibody can help confirm that the tumor is a carcinoma and make the distinction from a lymphoid lesion. A panel of neuroendocrine markers is useful, including CD56, chromogranin, and synaptophysin. TTF-1 is expressed in 70% to 80% of SCLC.⁶⁶ However, because TTF-1 can be positive in extrapulmonary small cell carcinomas, it should not be used to determine the primary site.⁷⁵ Ki-67 proliferation rate is very high, averaging 70% to 90%.⁷⁶

In up to 5% to 7% of cases, expert lung cancer pathologists disagree about the separation of SCLC and NSCLC.⁷⁷⁻⁷⁹ Agreement for the diagnosis of SCLCs for all five observers in one study was 93% and, for at least four of five observers, it was 98%.⁷⁸ When disagreements arise, it is best to use a consensus approach among other pathology colleagues. Extramural consultation may be needed if a consensus diagnosis cannot be reached locally. Comparison of problematic biopsy specimens with any available cytology specimens can be very helpful because the morphology is often easier to assess based on cytology.

One of the reasons small biopsy interpretation can be difficult is due to the frequent finding of “crush artifact,” a

Figure 14-10 Large cell neuroendocrine carcinoma. **A**, Peripheral palisading and rosette-like structures give this tumor a neuroendocrine morphologic appearance. The tumor cells have abundant cytoplasm with large hyperchromatic nuclei. Some of the nuclei show vesicular chromatin and/or prominent nucleoli. Mitoses are frequent. (H&E stain; original magnification $\times 200$.) **B**, The tumor cells are diffusely positive for synaptophysin (Immunohistochemistry for synaptophysin; original magnification $\times 400$.)

loss of cellular detail usually seen from the crushing of tumor cells by the biopsy forceps. The vast majority of tumors with dense sheets of small blue cells showing crush artifact turn out to be SCLC, perhaps indicating fragility of the SCLC tumor cells. However, a similar crush artifact can be seen in carcinoid tumors, lymphocytic infiltrates, or poorly differentiated NSCLC. In the context of extensive artifact, the diagnosis of SCLC requires that some preserved tumor cells with diagnostic morphology compatible with SCLC should be seen to confirm the diagnosis. Even in crushed specimens, immunohistochemical markers can be useful, because SCLC may demonstrate positive staining for cytokeratin, chromogranin, CD56, synaptophysin, TTF-1, and a high proliferation index with Ki-67.⁶⁶

In the setting of keratin-negative staining in a suspected SCLC, it is important to exclude other differential diagnoses such as chronic inflammation, lymphoma, primitive neuroectodermal tumor, or small round cell sarcoma.⁶⁶ However, the distinction of SCLC from non-SCLC is primarily based on morphology rather than any immunohistochemical or molecular marker.⁶⁶

Large Cell Neuroendocrine Carcinoma

In surgical series, *large cell neuroendocrine carcinoma* (LCNEC) comprises approximately 3% of resected lung cancers.^{80,81} LCNEC differs from typical and atypical carcinoid tumors in that it is a high-grade non–small cell neuroendocrine carcinoma. It is distinction from SCLC based on morphologic characteristics (Table 14-2 and see eTable 14-1).⁶⁶ The morphologic criteria include (1) neuroendocrine morphology: organoid, palisading, trabecular, or rosette-like growth patterns (see Fig. 14-10A); (2) non–small cell cytologic features: large size, polygonal shape, low nuclear to cytoplasmic ratio, coarse or vesicular nuclear chromatin, and frequent nucleoli; (3) high mitotic rate (11 or more per 2 mm²) with a mean of 60 mitoses per 2 mm²; (4) frequent

necrosis; (5) at least one positive neuroendocrine immunohistochemical marker or neuroendocrine granules seen on electron microscopy (see Fig. 14-10B).^{6,82} The diagnosis of LCNEC based on small biopsy specimens such as needle or bronchoscopic biopsy specimens is usually very difficult because the neuroendocrine morphology is hard to appreciate without a resection specimen. *Combined LCNEC* is the term used for LCNEC that are combined with other histologic types of NSCLC such as adenocarcinoma or squamous cell carcinoma (see Table 14-1).⁶

Typical and Atypical Carcinoid

Carcinoid tumors account for 2% to 3% of all invasive lung malignancies.¹³ Patients are asymptomatic at presentation in approximately 50% of cases.^{80,83,84} The mean age of presentation for *typical carcinoid* (TC) and *atypical carcinoid* (AC) tumors is 45 to 55 years without any sex predilection (Table 14-3). Carcinoids are the most frequent tumor of the lung in children.⁸⁵ The typical presenting symptoms are hemoptysis in 18%, postobstructive pneumonitis in 17%, and dyspnea in 2% of patients. Patients may present with paraneoplastic syndromes such as the carcinoid syndrome or Cushing syndrome.^{80,83,84} Surgical resection is the primary approach to treatment.^{80,83,84} TCs have a favorable prognosis.^{80,83,84} Because 5% to 20% of TCs have regional lymph node involvement, this feature should not be used to make a distinction from AC.^{80,83,84} ACs have a larger tumor size and a higher rate of metastases than TCs, and patients have significantly worse survival; 5-year survival in AC is approximately 30%.^{80,83,84}

Carcinoid tumors may be central (see eFig. 54-7) or peripheral in location. Central tumors often have polypoid endobronchial growth, while peripheral carcinoids are usually subpleural. The classic histologic pattern consists of an organoid growth pattern and uniform cytologic features consisting of moderate eosinophilic, finely granular cytoplasm with nuclei possessing a finely granular chromatin pattern (Fig. 14-11). Both TC and AC can show a variety of histologic patterns, including spindle cell, trabecular, palisading, papillary, sclerosing papillary, rosette-like, glandular, and follicular patterns.⁸² Cytologically, the tumor cells may have acinic cell-like, signet-ring, mucin-producing, or melanocytic features.⁸²

Table 14-3 Typical and Atypical Carcinoid: Distinguishing Features		
Histologic or Clinical Feature	Typical Carcinoid	Atypical Carcinoid
Histologic patterns: organoid, trabecular, palisading, and spindle cell	Characteristic	Characteristic
Mitoses	Absent or < 2 per 2 mm ² in area of viable tumor	2 to 10 per 2 mm ² in area of viable tumor
Necrosis	Absent	Characteristic, usually focal or punctate
Nuclear pleomorphism, hyperchromatism	Usually absent, not sufficient by itself for diagnosis of atypical carcinoid	Often present
Regional lymph node metastases at presentation	5% to 15%	40% to 48%
Distant metastases at presentation	Rare	20%
Survival at 5 years	90% to 95%	50% to 60%
Disease-free survival at 10 years	90% to 95%	35%

Modified from Kreisman H, Wolkove N, Quoix E: Small cell lung cancer presenting as a solitary pulmonary nodule. *Chest* 101:225–231, 1992; Johkoh T, Muller NL, Pickford HA, et al: Lymphocytic interstitial pneumonia: thin-section CT findings in 22 patients. *Radiology* 212:567–572, 1999.

Figure 14-11 Typical carcinoid (TC). This tumor is growing in organoid nests and consists of uniform medium-sized cells with a moderate amount of eosinophilic cytoplasm. (H&E stain; original magnification $\times 200$.)

The diagnostic criteria for AC are a carcinoid tumor with mitoses between 2 and 10 per 2 mm^2 area of viable tumor or the presence of necrosis (Fig. 14-12).^{6,86} In TC, mitotic figures are rare (<2 per 2 mm^2) and necrosis is absent.^{6,86} Pleomorphism, vascular invasion, and increased cellularity are not as helpful in separating TC from AC. These tumors usually stain strongly for neuroendocrine markers such as chromogranin, synaptophysin, and CD56. The proliferation rate for TC by Ki-67 is usually low ($\leq 5\%$) compared with the rate for AC, which is usually between 5% and 20%.^{76,87} In small crushed biopsies, Ki-67 can help separate TC or AC from the high grade LCNEC or SCLC where the proliferation rates are very high.^{76,87}

Preinvasive Lesion

Diffuse Idiopathic Pulmonary Neuroendocrine Cell Hyperplasia. Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia is a rare condition in which the peripheral airways are diffusely involved by neuroendocrine cell hyperplasia and tumorlets (Fig. 14-13).⁸⁸⁻⁹⁰ The clinical presentation resembles ILD manifest by airway obstruction due to bronchiolar fibrosis in approximately half of patients.⁸⁸⁻⁹⁰ The remaining patients typically present with multiple incidentally discovered pulmonary nodules, often found during follow-up for an extrathoracic malignancy. Because carcinoid tumors are frequently found in patients with diffuse idiopathic pulmonary neuroendocrine cell hyperplasia and the tumors are often multiple, this is thought to represent a preinvasive lesion for carcinoid tumors.^{6,89} There is a distinctive CT appearance consisting of centrilobular nodules and pulmonary nodules that correspond to the tumorlets and carcinoid tumors, respectively. Furthermore, in patients who present with clinical manifestations of ILD, the chest CT can be normal or it can show mosaic perfusion from air trapping, bronchial wall thickening, and bronchiectasis.⁸⁸⁻⁹⁰

LARGE CELL CARCINOMA

According to the US NCI SEER data, large cell carcinoma comprises 3% of all lung carcinomas, which is a

Figure 14-12 Atypical carcinoid (AC). **A**, Punctate foci of necrosis are present in the center of several organoid nests of uniform tumor cells. Necrosis is a feature characteristic of ACs. (H&E stain; original magnification $\times 200$.) **B**, The tumor cells are uniform, with moderate spindle-shaped cytoplasm, and the nuclear chromatin is finely granular. A single mitosis is present (arrow). (H&E stain; original magnification $\times 800$.)

Figure 14-13 Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia. This bronchiole shows mild fibrotic thickening of the wall, mucus in the lumen, and increased numbers of neuroendocrine cells in the mucosa. At the base of the mucosa are numerous neuroendocrine cells (arrow). (H&E stain; original magnification $\times 200$.)

Figure 14-14 Large cell carcinoma. This tumor consists of sheets and nests of large cells with abundant cytoplasm and vesicular nuclei with prominent nucleoli. (H&E stain; original magnification $\times 400$.)

marked decrease from 9% previously reported for 1983–1987.^{6,13,90a} Large cell carcinomas present most often in the lung periphery and are usually large necrotic tumors. The diagnosis of large cell carcinoma is one of exclusion, where the presence of squamous cell or glandular differentiation could not be seen by light microscopy. The microscopic appearance consists of sheets and nests of large polygonal cells with vesicular nuclei and prominent nucleoli (Fig. 14-14).⁶ Because solid adenocarcinoma requires a minimum of five mucin-positive cells in at least two high-power fields, in large cell carcinoma, the number of mucin-positive cells should be less than this.

A surgical resection specimen with thorough histologic sampling is required for the diagnosis of large cell carcinoma, therefore the diagnosis cannot be made based on a small biopsy or cytology specimen because an adenocarcinoma or squamous cell carcinoma component cannot be excluded.⁶ Tumors that historically have been classified as large cell carcinoma in the setting of advanced lung cancer would be best classified as NSCLC-NOS according to the 2011 IASLC/ATS/ERS lung adenocarcinoma classification.^{4,14,52,91} If immunostains are performed, some of these tumors might be reclassified as NSCLC, favor adenocarcinoma, or NSCLC, favor squamous cell carcinoma, and a small percent would remain as NSCLC-NOS.^{4,14} The adenocarcinoma phenotype cases show driver mutations in 38% of cases that are typical of adenocarcinoma, including *KRAS*, *BRAF*, *ALK*, *EGFR*, *MAP2K1*, and *PIC3CA*.⁹²

ADENOSQUAMOUS CARCINOMA

Adenosquamous carcinoma accounts for 1% of all lung cancers in the United States.¹³ The diagnosis of adenosquamous carcinoma requires the presence of at least 10% squamous cell and adenocarcinoma components as seen on light microscopy.^{6,93-95} The diagnosis of adenosquamous carcinoma may be suspected but cannot be made by small biopsy or cytology because a larger resection specimen is needed.

CARCINOMAS WITH PLEOMORPHIC, SARCOMATOID, OR SARCOMATOUS ELEMENTS

The rarest histologic subgroup of major lung cancers is that of sarcomatoid carcinomas, which comprise 0.5% of all invasive lung malignancies in the United States.¹³ These poorly differentiated tumors consist of a spectrum of lung carcinomas with pleomorphic, sarcomatoid, and sarcomatous elements with poor prognosis.^{6,96} Most pleomorphic carcinomas are large peripheral tumors that frequently invade the chest wall.^{6,96} The diagnosis of pleomorphic carcinomas requires the presence of at least a 10% component of a spindle cell and/or giant cell component as well as a carcinomatous component that may consist of a single or mixture of patterns of other histologic types such as adenocarcinoma and/or squamous cell carcinoma.^{6,96}

In small biopsies or cytology specimens, one can only suggest the diagnosis of pleomorphic carcinoma because this diagnosis requires a resection specimen. Carcinomas with a pure giant cell or spindle cell pattern are classified as giant cell or spindle cell carcinoma, respectively. Giant cell carcinomas are composed of huge bizarre pleomorphic and multinucleated tumor giant cells.^{6,96} The diagnosis of pleomorphic carcinoma can be made by light microscopy but immunohistochemistry, particularly for epithelial markers such as keratin, can be helpful in confirming epithelial differentiation in poorly differentiated tumor components.^{6,96}

Carcinosarcoma and Pulmonary Blastoma

According to the 2004 World Health Organization classification, tumors composed of a mixture of carcinoma and sarcoma that show heterologous elements such as malignant cartilage, bone, or skeletal muscle are classified as carcinosarcoma.^{6,96} Pulmonary blastomas are composed of a glandular component with a fetal adenocarcinoma pattern and a primitive sarcomatous component with blastomatous stroma. These tumors are now distinguished from fetal adenocarcinoma, which are classified as a variant of adenocarcinoma.^{6,80,83,84,96}

PLEURAL TUMORS

SOLITARY FIBROUS TUMOR

Solitary fibrous tumors of the pleura are localized neoplasms arising in the pleura that are usually benign, with a small percentage that are malignant. About 80% arise on the visceral pleura, with a minority arising from the parietal pleura or rarely from the pulmonary parenchyma. These tumors are not mesothelial in origin. They are derived from submesothelial connective tissue and are not related to asbestos.

The majority of tumors are large, measuring over 10 cm in diameter, and often have a pedicle.^{6,97,98} The tumors are gray-white, with a nodular, whorled, or lobulated appearance (Fig. 14-15A; see eFig. 56-11E).

Histologically the tumors most often show a “patternless pattern” of disorderly or randomly arranged mixtures of spindle to oval shaped cells with a ropy collagenous stroma (see Fig. 14-15B). Criteria for malignancy include increased

Figure 14-15 Fibrous tumor of the pleura. **A**, The tumor is circumscribed with a whorled, tan, cut surface. **B**, The tumor cells are round to oval and spindle shaped, with a dense eosinophilic or “ropy” collagen stroma. (H&E stain; original magnification $\times 200$.) **C**, The tumor cells stain strongly for CD34. (CD34 immunohistochemistry; original magnification $\times 200$.)

cellularity, pleomorphism, necrosis, and more than four mitoses per 10 high-power fields. Immunohistochemical stains for CD34 and BCL2 are positive.

MALIGNANT MESOTHELIOMA

Malignant mesothelioma is a malignant neoplasm that can have an epithelioid, sarcomatoid, or biphasic appearance.^{6,99,100} These tumors have a characteristic gross appearance with diffuse pleural thickening. The tumor typically does not invade the lung parenchyma except for spread along the interlobar fissures. Microscopically, classic mesotheliomas show both epithelial and sarcomatoid patterns (Fig. 14-16).^{6,99} The epithelioid tumors consist of glands, tubules, and solid sheets of tumor cells with abundant eosinophilic cytoplasm. The sarcomatoid tumors are composed of sheets of spindle cells that are similar to a fibrosarcoma. Biphasic mesotheliomas should have at least 10% of each component.

Immunohistochemistry plays an important role in the diagnosis of malignant mesothelioma, in particular to help make the distinction with carcinomas that metastasize to the pleura.^{100,101} Both mesotheliomas and carcinomas are positive for cytokeratins. Mesotheliomas are usually positive for calretinin, WT-1, and D2-40 (podoplanin), while adenocarcinomas are typically negative.^{6,99} Adenocarcinomas often, express carcinoembryonic antigen, Leu-M1, B72.3, and BER-EP4, while mesotheliomas are negative for these markers. Historically the absence of mucin and the presence of hyaluronic acid (positive Alcian blue staining) and long, slender microvilli seen on electron microscopy have been used to support the diagnosis of malignant mesothelioma, but immunohistochemistry has largely replaced these studies.^{6,99} See Chapter 82 for additional information on tumors of the pleura.

INTERSTITIAL LUNG DISEASES

IDIOPATHIC INTERSTITIAL PNEUMONIAS

The term *interstitial lung disease* comprises a heterogeneous group of disorders with various histopathologic features. Many different etiologies have very similar or identical pathologic ILD features and require thorough clinical and radiologic correlation to resolve. The differential diagnosis for most pathologic patterns includes collagen vascular disease, drug reaction, hypersensitivity reaction, or an idiopathic process.¹⁰²⁻¹⁰⁴ Therefore, the primary task of the pathologist is usually to recognize and categorize the pathologic pattern to expedite the correct clinical workup, inform treatment decisions, and guide prognosis. There may be histologic clues that can point toward an underlying etiologic process, as discussed in each subsequent section.

There have been various classifications of ILD, starting in 1969 by Liebow and Carrington.¹⁰⁵ In 2002, an ATS/ERS consensus classification of *idiopathic interstitial pneumonias* (IIP) was published.¹⁰⁶ Since then, there have been numerous publications and studies that have added significantly to our understanding of this category of disease with important clinical implications for management and treatment of patients with diffuse parenchymal lung disease. The ATS/ERS IIP classification was recently updated

Figure 14-16 Pleural malignant mesothelioma. **A**, The lung is encased by a dense pleural tumor that extends along the interlobar fissures but does not involve the underlying lung parenchyma. **B**, This epithelioid malignant mesothelioma is composed of sheets of epithelioid malignant tumor cells. (H&E stain; original magnification $\times 200$.) **C**, This sarcomatoid malignant mesothelioma is composed of mostly spindle-shaped malignant cells (H&E stain; original magnification $\times 200$.)

by an international multidisciplinary panel comprising pulmonologists, pathologists, radiologists, and molecular biologists.¹⁰⁷ IIPs were divided into four groups: (1) fibrosing, (2) acute/subacute, (3) smoking-related, and (4) a new subcategory of “rare IIPs” was introduced and now includes *lymphocytic interstitial pneumonia* (LIP) and the newly described entity pleuropulmonary fibroelastosis.¹⁰⁷ The rare histologic patterns acute fibrinous and *organizing pneumonia* (OP) and bronchiolocentric patterns of interstitial pneumonia are recognized, but there was insufficient evidence to accept these as distinct IIPs.

In cases that prove impossible to classify, the term *unclassifiable interstitial pneumonia* has been coined. It accounts for cases with inadequate clinical or radiologic data or an inadequate or nondiagnostic biopsy. It is also the suggested diagnosis when there is a major discrepancy between clinical, radiologic, and pathologic findings, when previous therapy has resulted in alterations in the radiologic or histologic findings, or when there are discrepancies between histologic findings in different lobes not resolved after correlation with clinical and radiologic data.¹⁰⁸ Additional information on IIPs is found in Chapter 63.

Fibrosing Interstitial Lung Disease

Usual Interstitial Pneumonia/Idiopathic Pulmonary Fibrosis. UIP is the most common pattern of ILD and is the pathologic hallmark of *idiopathic pulmonary fibrosis* (IPF). The incidence of IPF, the idiopathic form of UIP, is 7 to 20 per 100,000 people and has no geographic or ethnic predilection.^{109,110} The classic clinical presentation is the gradual onset of shortness of breath with cough and clubbing in up to 50% of cases.^{104,111} Pulmonary hypertension has been reported in up to 32% of IPF patients awaiting lung transplantation and is associated with higher mortality in comparison to patients without pulmonary hypertension.¹¹² Radiographic imaging studies reveal small lung volumes with bilateral coarse reticular opacities most pronounced in the subpleural lower lobes and lower portions of the upper lobes (see Figs. 63-6 and 63-7). Honeycomb changes and traction bronchiectasis are typical features and become more pronounced as the disease progresses. When these typical features are present, the high-resolution CT appearance is 90% specific for UIP and surgical biopsy is often deferred (see Fig. 63-11 and eFigs. 63-2 through 63-5 and 63-7).^{104,106,113-115} A highly probable diagnosis of IPF can be made without lung biopsy, but definitive diagnosis of IPF requires surgical lung biopsy and exclusion of other known causes of ILD. It is important for the treating clinician to perform a thorough workup, including exposure history and serologic studies, to exclude secondary causes of pulmonary fibrosis such as chronic *hypersensitivity pneumonitis* (HP), collagen vascular disease, drug-toxicity, asbestosis, chronic aspiration, and Hermansky-Pudlak syndrome because each of these entities can cause an UIP pattern of interstitial fibrosis.^{102,103,116-118} Furthermore, after a biopsy has been performed and a pathologic diagnosis rendered, it is important to correlate the radiographic features with the pathologic findings in that cases of histologic UIP might not be associated with typical high-resolution CT findings of UIP. In this setting, multidisciplinary discussion is required for some of these patients to generate the correct diagnosis of IPF.^{104,106,107}

UIP is a diffuse fibrosing lung disease with a characteristic distribution of disease (see Fig. 63-22). The fibrosis is worse in the lower lobes and the lower portions of the upper lobe. Grossly, the pleura is firm and thickened with a cobblestone appearance. The histologic hallmark of UIP is the *heterogeneity* of the interstitial fibrosis, both in space and in time. As evidence of *spatial* heterogeneity, there should be areas of fibrosis separated by areas of more normal lung. Areas of normal lung should be present in a biopsy specimen to support the diagnosis and exclude other interstitial diseases. The fibrosis is distributed at the periphery of the lobules and is most pronounced in the subpleural regions (Fig. 14-17A). As evidence of *temporal* heterogeneity, there are areas of long-standing older interstitial fibrosis and areas of newer fibrosis characterized by *fibroblastic foci* (see Fig. 14-7B-C; see Fig. 63-24). Fibroblastic foci are composed of crescent shaped protrusions of fresh glycosaminoglycan-rich fibroblastic tissue composed of plump fibroblast and myofibroblasts. Fibroblastic foci are located in areas of ongoing or recent lung injury and are distinguished from older areas of denser fibrosis. Because the presence of numerous fibroblastic foci correlates with faster disease progression and decreased survival time, it is important to qualify the number of the fibroblastic foci in the surgical pathology report.¹¹⁹ The older areas of fibrosis are marked by architectural distortion of the underlying lung parenchyma with eventual development of honeycomb changes. There may be occasional aggregates of chronic inflammatory cells in the areas of older fibrosis but this does not tend to extend into normal-appearing lung parenchyma. Honeycomb changes are areas of abnormal dilatation of air spaces lined by bronchiolar epithelium (see Fig. 63-25). The cystic honeycomb spaces are filled with thick mucin-containing acute inflammatory cells; however, the presence of the neutrophils does not indicate an infectious process. Other characteristic features in the areas of older fibrosis and scarring include smooth muscle hyperplasia, pulmonary arterial thickening, and traction bronchiectasis. There should be no, or minimal, granulomatous inflammation, eosinophilia, acute pleuritis, or significant exogenous inorganic dust, silica, or asbestos fibers.^{102,104,106,110,111,120}

Acute exacerbation of IPF is a common but not well understood phenomenon. Acute exacerbation is the development of severe acute lung injury on a background of interstitial fibrosis and has been reported in several of the fibrosing ILDs. Five percent to 10% of patients annually develop acute respiratory worsening. Diagnostic criteria include (1) previous or concurrent diagnosis of IPF, (2) unexplained worsening or development of dyspnea within 30 days, (3) high-resolution CT demonstration of new bilateral ground-glass abnormality and/or consolidation superimposed on a background UIP pattern (see eFig. 63-11), (4) no evidence of pulmonary infection, and (5) exclusion of alternative causes, including left heart failure, pulmonary embolism, or other identifiable cause of acute lung injury. The histologic hallmark is the presence of acute lung injury with diffuse alveolar and/or OP superimposed on more established fibrosis. The histologic picture may be confusing especially when clinical or radiologic information is lacking or when acute exacerbation is the first presentation for the patient. However, the recognition of the older fibrotic injury, including honeycomb changes,

Figure 14-17 Usual interstitial pneumonia (UIP). **A**, Gross image shows lower lobe and periphery of upper lobe are replaced by pale fibrotic tissue displaying cystic honeycomb changes. The adjacent normal lung is spongy with preserved architecture. **B**, The areas of dense fibrosis contain honeycomb changes (top right) and sparse cellular inflammation. The transition with normal lung is abrupt (H&E stain; original magnification $\times 20$). **C**, The crescent-shaped fibroblastic focus is composed of loose and immature fibrous tissue (arrows). (H&E stain; original magnification $\times 200$.)

together with the acute lung injury helps establish the correct diagnosis.¹²¹⁻¹²⁵

As discussed previously, several entities can manifest a UIP pattern of fibrosis in the lungs, including chronic HP, collagen vascular disease involving the lungs, chronic aspiration, drug toxicity, asbestosis, and Hermansky-Pudlak syndrome. Clinical and radiologic evaluation often reveals the underlying etiology and distinguishes a secondary process from IPF. However, there may be some diagnostic uncertainty and pathologic evaluation may give clues as to the underlying etiology. Chronic HP is always associated with peribronchiolar metaplasia and most cases have demonstrable poorly formed granulomas. Collagen vascular disease may have pleural inflammation, prominent interstitial cellular infiltrates, and other features (Table 14-4). Chronic aspiration has sequelae of chronic airway irritation, specifically peribronchiolar metaplasia, and may have foreign material and giant cells or granulomas. Drug toxicity may have nonspecific histologic features but the accumulation of foamy macrophages could suggest amiodarone toxicity. Asbestosis is initially bronchocentric; iron stains may reveal ferruginous bodies diagnostic of asbestos. Hermansky-Pudlak syndrome is most commonly seen in albino people of Puerto Rican heritage; in this syndrome, vacuolated type II pneumocytes and alveolar macrophages are demonstrated.^{102,116,118,119,126-131} Features of usual interstitial pneumonia in patients with primary Sjögren's syndrome compared with idiopathic pulmonary fibrosis.^{131a} Drug toxicity and Hermansky-Pudlak syndrome may have similar histologic features, but clinical findings easily distinguish the two.

Nonspecific Interstitial Pneumonia. The term *nonspecific interstitial pneumonia* (NSIP) was first coined to

describe a pattern of ILD associated with HIV infection.¹³² Subsequently, Katzenstein and Fiorelli used the term to describe a *specific* pattern of ILD distinct from UIP that has since been found to have differing clinical and epidemiologic features.¹³³⁻¹³⁵ Katzenstein and Fiorelli grouped NSIP into three categories: group I, predominance of interstitial inflammation (cellular); group II, mixture of inflammation and fibrosis (mixed cellular and fibrotic); group III, primarily interstitial fibrosis (fibrotic).¹³³ When NSIP was introduced in the ATS/ERS Idiopathic Interstitial Pneumonia classification in 2002, it was given a provisional status due to uncertainties about the entity.¹⁰⁶ It has since become established as a specific pattern of ILD and found to be associated with secondary etiologies. Recent studies suggest most cases of NSIP pattern ILD are secondary to autoimmune disease, chronic HP, drug reactions, or organizing *diffuse alveolar damage* (DAD) and relatively few cases are truly idiopathic.¹³⁴⁻¹³⁷ Therefore, when the pattern of NSIP is recognized, a search for secondary causes of ILD is recommended because there may be significant differences in treatment and prognosis from idiopathic cases.

Compared to patients with UIP, patients with NSIP tend to be younger—average age 52 years—and are more likely to be female.¹³⁵ This gender difference may reflect the strong association with collagen vascular disease that tends to affect middle aged and younger women. Patients with NSIP secondary to collagen vascular disease often have serologic studies disclosing positive antinuclear antibody or rheumatoid factor.^{134,135,137} Imaging studies demonstrate bilateral reticular opacities with or without ground-glass opacifications, predominantly in the lower lobes.^{114,138,139}

In contrast to that of UIP, the pattern of interstitial disease associated with NSIP is generally uniform in space and in time. Grossly, the transition from fibrotic to normal lung is more gradual and does not display the very prominent honeycomb changes that characterize UIP (Fig. 14-18A). Histologically, the interstitial pneumonia is evenly distributed throughout the lobules without accentuation around the airways or in the subpleural regions (see Fig. 14-18B-C). The degree of cellular infiltration is variable and inversely related to fibrosis. In cellular NSIP, the interstitium is expanded by lymphocytes with scattered histiocytes and rare eosinophils and neutrophils (see Fig. 63-27). The presence of numerous eosinophils or frequent granulomas would indicate a secondary cause of NSIP. In fibrotic NSIP, the interstitium is expanded by fibrosis but the even distribution throughout the lobule is the same as in cellular NSIP (see Fig. 63-28). In mixed cellular and fibrotic NSIP, there is a gradual transition between cellular and fibrotic infiltrates. There is rarely the development of honeycomb changes and only in advanced cases of interstitial fibrosis. When honeycomb changes develop, the overall prognosis matches that of UIP.^{140,141} Similarly, fibroblastic foci are not a diagnostic feature of NSIP, but fibroblastic foci are not specific to UIP and the presence of rare fibroblastic foci does not exclude an NSIP pattern of fibrosis. Likewise, some degree of peribronchiolar metaplasia does not exclude the diagnosis of NSIP, because peribronchial metaplasia is often seen in the lungs of patients exposed to environmental irritants, especially cigarette smoke. OP is a nonspecific

Table 14-4 Histologic Features of Collagen Vascular Diseases in the Lungs	
Rheumatoid arthritis	Pleuritis, chronic interstitial pneumonia (NSIP pattern > UIP pattern), DAD, LIP, OP, necrobiotic (rheumatoid) nodule, amyloid, vasculitis, bronchiolitis, DAH
Systemic lupus erythematosus	Pleuritis, chronic interstitial pneumonia (NSIP > UIP), DAD with immune complex deposits, OP, vasculitis, bronchiolitis, DAH
Scleroderma	Pleuritis, chronic interstitial pneumonia (NSIP > UIP), DAD, OP, aspiration pneumonia, pulmonary hypertension including plexiform lesions
Polymyositis/dermatomyositis	Pleuritis, chronic interstitial pneumonia (NSIP > UIP), DAD, OP, aspiration pneumonia, vasculitis, bronchiolitis
Sjögren syndrome	Pleuritis, chronic interstitial pneumonia (NSIP pattern > UIP pattern), LIP, OP, amyloid, vasculitis, bronchiolitis
Mixed connective tissue disease	Pleuritis, chronic interstitial pneumonia (NSIP pattern > UIP pattern), DAD, LIP, OP, necrobiotic (rheumatoid) nodule, aspiration pneumonia, amyloid, vasculitis, bronchiolitis, DAH

DAD, Diffuse alveolar damage; DAH, diffuse alveolar hemorrhage; LIP, lymphocytic interstitial pneumonia; NSIP, nonspecific interstitial pneumonia; OP, organizing pneumonia; UIP, usual interstitial pneumonia.

Figure 14-18 Nonspecific interstitial pneumonia. **A**, Gross image shows gradual transition of fibrosis from lower lobe to upper lobe with patchy normal lung. **B**, Low-power view of fibrotic interstitial infiltrate with preservation of alveolar architecture. (H&E stain; original magnification $\times 40$.) **C**, High-power view of mixed cellular and fibrotic infiltrate with temporal and spatial homogeneity.

reaction to lung injury and may be present in NSIP but it should not be widespread.¹⁴¹

As mentioned previously, the NSIP pattern of ILD may be seen secondary to numerous etiologies (Table 14-5). Before attempting to determine the underlying cause of the disease, it is important to distinguish NSIP from UIP. The distribu-

tion of the fibrosis and presence or absence of heterogeneity aids the correct diagnosis. However, if both patterns of ILD are present, the disease tends to behave as UIP, a factor that should guide management.¹²⁰ The particular pattern of NSIP also influences prognosis and treatment. Cellular NSIP has an excellent 5-year survival, with one study showing 100% survival.¹³⁴ Fibrotic NSIP has worse survival but is still much better than UIP unless honeycomb changes develop. In this setting, the survival equals that of UIP.^{114,141}

Acute/Subacute Interstitial Lung Disease

Organizing Pneumonia/Cryptogenic Organizing Pneumonia. OP is a nonspecific reparative reaction to many forms of lung injury and has been the source of some confusion over the years. OP may be encountered most commonly as a secondary reactive process, but occasionally it may be an idiopathic lesion. The clinical implications of discovering the cause of OP are very important. If the OP is associated with an autoimmune process or is idiopathic, the primary treatment will be immunosuppression; if the etiology is infectious, the treatment would be antibiotics and not immunosuppression. The confusion has been caused to some degree by the use of the name for the idiopathic disease with the histologic lesion and the similarity with an unrelated disease, *bronchiolitis obliterans*. To alleviate some of the misunderstanding, the older term for idiopathic OP, *bronchiolitis obliterans organizing pneumonia*, has been replaced with the term *cryptogenic organizing pneumonia* (COP) in the most current ATS/ERS classification.¹⁰⁶ Therefore, emphasis has been made in the latest ATS/ERS classification to use the term *organizing pneumonia* for the histologic lesion and to reserve the term COP as a clinical diagnosis of exclusion.

Patients with COP often present with fevers, chills, night sweats, and dyspnea with a dry cough. Chest imaging typically shows bilateral ground-glass opacities with air bronchograms and lower lobe predominance in most patients (see Fig. 63-33, eFigs. 63-21 and Video 63-2).¹⁴²⁻¹⁴⁴ Microscopically, OP is characterized by polypoid plugs of fresh fibrotic tissue that often develop in small airways (see Fig. 63-35) but also extend into alveolar ducts and sacs. In the idiopathic form, there is minimal cellular inflammation and no significant interstitial fibrosis^{102,145} (Fig. 14-19). If there is prominent inflammation, significant acute lung injury or interstitial fibrosis, then the OP is much more likely secondary to the disease process that is affecting the lungs. Special stains may be useful to evaluate for infections.^{145,146}

Figure 14-19 Cryptogenic organizing pneumonia (COP). Patchy foci of organizing pneumonia in absence of significant interstitial inflammation and fibrosis, characteristic of COP. (H&E stain; original magnification $\times 40$.)

Diffuse Alveolar Damage/Acute Interstitial Pneumonia. DAD is the histologic picture of severe acute lung injury and may be secondary to numerous pulmonary insults. This is the common pathologic diagnosis of patients with clinical acute respiratory distress syndrome. *Acute interstitial pneumonia* (AIP) is the idiopathic form of DAD. In this setting, there is no identifiable cause for the acute lung injury and is a diagnosis of exclusion. AIP is a rare syndrome and clinically presents as severe and sudden respiratory distress in a previously healthy individual. Mortality is greater than 50%. AIP is a diagnosis of exclusion and requires an extensive clinical workup to exclude infections or other identifiable pulmonary insults, such as drug toxicity, collagen vascular disease, radiation injury, or trauma.^{102,106,147}

The radiographic and pathologic features vary depending on the stage of the disease. Early, imaging studies reveal diffuse ground-glass opacities with increased densities in dependent parts of the lung (see [eFigs. 63-19](#) and [63-20](#)). Initially, there is no architectural remodeling or traction bronchiectasis. After 2 to 3 weeks, during the later stages, reticular opacities may become more pronounced and traction bronchiectasis and cystic changes may develop.^{148,149}

Pathologically, during the early exudative stage, the alveolar wall is thickened by interstitial edema and neutrophil margination in capillaries. Pneumocytes become hypertrophied and may undergo type II pneumocyte hyperplasia. Grossly, the lungs are heavy and boggy with a dark red cut surface. Toward the end of the first week, alveolar exudates increase and develop. The hyaline membranes are linear accumulations of dense hyaline material composed of fibrin, cellular debris, and serum proteins that line the surface of the alveolar sacs ([Fig. 14-20A](#), see [Fig. 63-32](#)). Small arteries and arterioles often contain in situ thrombi in the areas of acute lung injury. The underlying lung architecture is initially normal if the patient did not have preceding lung disease. In the later organizing stage that develops after 2 to 3 weeks, OP emerges and begins to replace the hyaline membranes (see [Fig. 14-20B](#)). Concurrently, fibrosis develops in the alveolar walls and may eventually result in an NSIP pattern of interstitial fibrosis. The

Figure 14-20 Diffuse alveolar damage (DAD). **A**, Hyaline membranes (arrows) line alveolar walls that are swollen with edema and scattered inflammatory cells. Pneumocytes are swollen and appear reactive. (H&E stain; original magnification $\times 40$.) **B**, Organizing diffuse alveolar damage shows loss of hyaline membranes with development of early fibrosis in the interstitium. There is only paucicellular inflammation. (H&E stain; original magnification $\times 400$.)

fibrosis may cause traction bronchiectasis and microcystic formation. The gross lungs in late stage DAD/AIP become firm and fibrotic with small cystic changes. In contrast to UIP/IPE, the lungs are normal in size but are heavy.^{106,147,150}

In AIP, the DAD has relatively mild cellular inflammation. The presence of certain pathologic features may suggest an etiology; clusters of neutrophils, necrotizing granulomas, or viral inclusions would indicate an infectious etiology; neutrophils, necrotizing granulomas, and tissue necrosis with or without vasculitis may also be due to vasculitis; foreign material with or without giant cells suggests aspiration pneumonia; pleural inflammation may indicate a collagen vascular disease; eosinophilia may suggest acute eosinophilic pneumonia; and accumulation of foamy histiocytes or foamy cytoplasmic changes in pneumocytes may suggest a drug toxicity. Clinical studies, including microbiologic cultures and serologic correlation for vasculitis and collagen vascular disease markers, may disclose a secondary etiology.

In some cases of diffuse fibrotic lung disease, especially UIP/IPF, acute exacerbation develops. Pathologically, this resembles organizing DAD superimposed on a background of diffuse interstitial fibrosis.^{121,122}

Smoking-Related Interstitial Lung Disease

Smoking is the primary etiology for two patterns of ILD, *respiratory bronchiolitis-ILD* (RB-ILD) and *desquamative interstitial pneumonia* (DIP), which are considered ends of a spectrum of lung disease characterized by accumulation of pigmented macrophages, mild to moderate interstitial fibrosis, and chronic airway inflammation. In RB-ILD, the macrophages are centered on and around small airways and, in DIP, the macrophages are more diffusely distributed throughout entire lobules. Between individual cases, some features may overlap; nevertheless, in general, the clinical, radiologic, pathologic, and treatment characteristics are different and the entities remain separately classified.¹⁰⁶

Respiratory Bronchiolitis-Interstitial Lung Disease.

RB-ILD is the pathologic manifestation of chronic airway inflammation, usually due to smoking, and reactive/reparative changes in and around the small airways. In clinical practice, the diagnosis is based on a history of smoking, dyspnea, ground-glass opacities with centrilobular nodules on imaging (see eFig. 63-16), and accumulation of pigmented (smokers') macrophages on *bronchoalveolar lavage* (BAL) fluid. Surgical biopsies are not performed as part of the workup unless there is concern for another process. The two histologic features of RB are peribronchiolar metaplasia of alveolar ducts surrounding terminal and respiratory bronchioles and accompanying clusters of pigmented macrophages (Fig. 14-21; see Fig. 63-30). When RB is associated with clinical features of ILD, the clinical disease is termed *respiratory bronchiolitis-interstitial lung disease*.

RB-ILD is almost always associated with smoking or another environmental irritant and is usually found in association with centrilobular emphysema. RB is a frequent incidental finding in lung excision specimens and is especially common in patients with a smoking history. Peribron-

chiolar metaplasia is a nonspecific reaction to chronic airway inflammation and is a very prominent feature of chronic HP. In contrast to chronic HP, RB usually has more conspicuous pigmented macrophages, is not associated with granulomas, and does not have lymphocytosis on BAL fluid analysis.¹⁵¹⁻¹⁵⁵

Desquamative Interstitial Pneumonia. DIP is another ILD strongly associated with smoking and is always associated with RB. DIP is an increasingly uncommon entity but has been observed in nonsmokers. It presents as dyspnea with cough and reveals bilateral ground-glass opacities with reticular markings (see eFig. 63-17) corresponding to interstitial fibrosis. Histologically, DIP is characterized by sheets of pigmented (smokers') macrophages that fill alveolar spaces and tend to clump together (see Fig. 63-31). There are usually clusters of eosinophils, but these are greatly outnumbered by the macrophages and are not sufficient to suggest eosinophilic pneumonia (Fig. 14-22). There is usually interstitial fibrosis within alveolar septa that resembles fibrotic NSIP and is more extensive than the microscopic interstitial fibrosis associated with smoking-related centrilobular emphysema.^{151,152,156-160}

The symptoms of DIP usually respond to smoking cessation and steroids when necessary, but a minority of patients fail to respond to treatment.

Rare Idiopathic Interstitial Pneumonias

To accommodate the introduction of newly described rare entities and to classify idiopathic LIP, a new subcategory of "rare IIP" was created in the latest ATS/ERS IIP classification.

Lymphocytic Interstitial Pneumonia. LIP is a rare entity most often associated with infections or underlying autoimmune or immunodeficiency diseases but can be idiopathic. Secondary causes include rheumatoid arthritis, Sjögren syndrome, lupus, Hashimoto thyroiditis, myasthenia gravis, common variable immunodeficiency, allogeneic bone marrow transplantation, and viral infections. Viruses implicated in LIP include *human immunodeficiency virus 1*

Figure 14-21 Respiratory bronchiolitis (RB). Small bronchiole with luminal pigmented macrophages (arrows) and peribronchiolar metaplasia. (H&E stain; original magnification $\times 200$.)

Figure 14-22 Desquamative interstitial pneumonia (DIP). Diffuse accumulation of pigmented macrophages in alveolar spaces throughout lobule (arrows). There is diffuse interstitial fibrosis in a nonspecific interstitial pneumonitis pattern (H&E stain; original magnification $\times 100$.)

Figure 14-23 Lymphocytic interstitial pneumonia (LIP). The interstitium is greatly expanded by a dense lymphoplasmacytic infiltrate with loss of alveolar spaces. In less involved areas, the architecture is maintained. (H&E stain; original magnification $\times 40$.)

(HIV-1), *human T-cell lymphotropic virus 1* (HTLV-1), and *Epstein-Barr virus* (EBV) (especially in children). Clinically, LIP presents with cough, fever, and dyspnea; imaging studies may show various findings, including ground-glass opacity (see eFig. 63-28), nodules (see eFig. 63-29), bibasilar interstitial infiltrates, cysts (see Fig. 63-36 and eFig. 63-30), and honeycomb changes in up to one third of patients.¹⁶¹⁻¹⁶⁶

Pathologically, the interstitium is greatly expanded by a dense lymphoplasmacytic infiltrate (see Fig. 63-37) that is most pronounced in the lower lobes and is evenly distributed throughout the lobules (Fig. 14-23). The pattern resembles cellular NSIP but is distinguished by a greater degree of cellular infiltrate that disrupts the normal underlying architecture that is usually maintained in NSIP. Eventually, fibrosis with honeycomb changes may develop. The lymphoid infiltrate is nonneoplastic and consists of an organized mixture of T cells and nodular aggregates of B cells. However, secondary low grade lymphoma may develop in the setting of LIP in up to 30% of cases and is most commonly an extranodal marginal zone B cell lymphoma. LIP-associated lymphomas need to be distinguished from pseudolymphoma, another associated finding in LIP that is a localized masslike variant of LIP, which is polyclonal and shows no evidence of malignancy by immunohistochemistry or flow cytometry.^{102,167,168}

A newly described category of secondary LIP is granulomatous lymphocytic ILD that is associated with immunoglobulin deficiency, often common variable immunodeficiency. Pathologically and radiographically, it is very similar to LIP but is distinguished by the presence of numerous nonnecrotizing granulomas. The granulomas are not associated with infectious organisms but special stains should be performed to exclude an incidental infection in the setting of LIP.^{161,169}

Idiopathic Pleuroparenchymal Fibroelastosis. *Idiopathic pleuroparenchymal fibroelastosis* is a term recently coined to describe a rare entity of extensive upper lobe predominant fibroelastosis in the pleura and subpleura that is distinct from other forms of ILD. Clinically, patients are on

Figure 14-24 Pleuroparenchymal fibroelastosis. **A**, Low-power view showing extent of subpleural scar tissue. (H&E stain; original magnification $\times 20$.) **B**, Higher power showing sharp transition between scar and normal lung. The fibroelastic scar tissue is paucicellular and no fibroblastic foci are present. (H&E stain; original magnification $\times 40$.)

average 57 years old and have no gender predilection. Symptoms include dyspnea and cough. Imaging studies (see eFig. 63-31) show dense subpleural consolidations with upper lobe volume loss and possible architectural distortion with traction bronchiectasis in the involved lobes. The pathology is characterized by extensive fibroelastic scarring in the interstitium, entering into the alveolar space at the subpleural periphery of the lobules (Fig. 14-24). The transition between fibroelastosis and normal lung is very sharp and reminiscent of the spatial heterogeneity in UIP. However, fibroblastic foci are absent or rare in pleuropulmonary fibroelastosis, and the mild chronic inflammation present in UIP is virtually nonexistent in pleuropulmonary fibroelastosis. Despite the bland appearance of the fibrosis, the disease progresses in 60% of patients with eventual death in 40%.^{102,170-173}

Rare Histologic Patterns. The latest ATS/ERS classification includes a new category of rare histologic patterns to account for two relatively newly described entities, acute fibrinous and OP and bronchiolocentric interstitial pneumonia. Both of these entities share overlapping histologic

Figure 14-25 Acute fibrinous and organizing pneumonia. The alveolar spaces are occluded by rounded accumulations of fibrin and alveolar walls are edematous with reactive pneumocytes. (H&E stain; original magnification $\times 400$.)

Figure 14-26 Bronchiolocentric interstitial pneumonia. There is centrilobular scar with absence of granulomas and only focal and mild chronic inflammation. (H&E stain; original magnification $\times 40$.)

features with other well-defined entities, may be seen in association with numerous secondary etiologies, and may or may not represent true and distinctive idiopathic diseases. Nevertheless, it is useful to recognize the patterns because they can guide the diagnostic workup.

ACUTE FIBRINOUS AND ORGANIZING PNEUMONIA. Acute fibrinous and OP is a histologic pattern of lung injury that is associated with acute respiratory failure with a similar mortality rate to AIP. Imaging studies reveal bilateral basal ground-glass opacities and consolidations. The diagnostic histologic feature is the accumulation of rounded intra-alveolar fibrin that may merge with OP (Fig. 14-25). Pneumocytes are reactive with type II pneumocyte hyperplasia and accompanying interstitial and intra-alveolar edema with paucicellular inflammation. There are no hyaline membranes or granulomas and eosinophils should be inconspicuous.

It is not clear whether acute fibrinous and OP is a distinctive entity, a more aggressive form of COP, or a subacute or organizing pattern of AIP. As with other forms of acute/subacute lung injury, secondary causes should be considered in the etiology, including connective tissue disease, subacute hypersensitivity pneumonitis, infection, and drug reaction. If no etiologic cause is discovered by clinical studies or special stains, it may be considered an idiopathic process.¹⁷⁴⁻¹⁷⁷

BRONCHIOLOCENTRIC INTERSTITIAL PNEUMONIA. Bronchiolocentric interstitial pneumonia is characterized by centrilobular fibrosis with peribronchiolar metaplasia (Fig. 14-26). There is variable chronic inflammation but there are no granulomas, abscesses, or eosinophils. It may be histologically indistinguishable from chronic HP without granulomas; therefore, thorough clinical evaluation to rule out HP is essential before the clinical diagnosis can be considered. Patients are middle-aged with a female predominance and demonstrate restrictive pathophysiology on pulmonary function tests. The radiographic features include reticulonodular opacities and air trapping. The secondary etiologies include all entities that may induce chronic airway inflammation, especially chronic HP, con-

nective tissue disease, and chronic aspiration/inhalational injury.^{178,179}

OTHER INTERSTITIAL LUNG DISEASES

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis (HP), previously termed allergic extrinsic alveolitis, is an important and relatively frequently encountered cause of ILD. HP is a protean entity that has various presentations both clinically and pathologically. Other/older terms for HP include *farmer's lung*, *bird fancier's lung*, *humidifier lung*, *bat lung*, *coffee worker's lung*, and *pituitary snuff-taker's lung*, among many others. The various terms are derived from the source of the antigen that incites the autoimmune hypersensitivity reaction. More than 300 antigens have been implicated in the pathogenesis of HP. A fuller discussion of the pathogenesis of HP is found in Chapter 64.

HP may present at various stages. The traditional classification of HP separates the disease into acute, subacute, and chronic forms of HP. Acute HP is a transient process that results in chills, chest tightness, myalgia, headaches, cough, and dyspnea and lasts no more than a few days in the worst cases. Subacute and chronic cases of HP take longer to develop and are more associated with distinctive pathologic findings.¹⁸⁰

The pathology of acute HP is not well described because it is only rarely biopsied, and most case series are present in the older literature. Reports describe peribronchiolar cellular and air space edema with fibrinous exudates, consistent with organizing acute lung injury as well as neutrophilic infiltrates and capillaritis.^{176,181-183}

Subacute HP is primarily distinguished from chronic HP by the lack or paucity of well-established fibrosis. There is a dense lymphoplasmacytic interstitial infiltrate that is centered on, or accentuated around, the small airways. The bronchioles reveal cellular bronchiolitis that may include nodular lymphoid aggregates adjacent to the airways. Peribronchiolar metaplasia may not be fully developed in cases

Figure 14-27 Hypersensitivity pneumonitis (HP). **A**, Bronchiole demonstrates florid peribronchiolar metaplasia. The interstitium is mildly expanded by cellular infiltrate and a poorly formed granuloma is present in the left of the field. (H&E stain; original magnification $\times 100$). **B**, Small cluster of multinucleated giant cells in center of field (arrow). (H&E stain; original magnification $\times 200$.)

of subacute HP. One of the pathologic hallmarks of HP is the presence of poorly formed nonnecrotizing granulomas in the interstitium adjacent to the airways (Fig. 14-27A). The granulomas are composed of an irregularly circumscribed collection of epithelioid histiocytes with or without multinucleated giant cells. The giant cells may contain cholesterol clefts, oxalate crystals, Schaumann bodies, or asteroid bodies (see Fig. 14-27B). The reported incidence of granulomas has been quite variable and it is recognized that as the disease progresses, the granulomas become less prevalent while fibrosis becomes more established. In cases of subacute HP, granulomas can be found in up to 70% of cases.¹⁸²

Chronic HP is distinguished from less advanced forms by the presence and distribution of well-established interstitial fibrosis.¹⁸⁴ The pattern of fibrosis is variable and may resemble UIP, fibrotic NSIP, bronchiolocentric interstitial pneumonia, or unclassifiable interstitial fibrosis. Chronic HP is invariably associated with peribronchiolar metaplasia that becomes more florid as the case becomes more advanced. The absence of peribronchiolar metaplasia should cause reconsideration of this diagnosis. As with other forms of

chronic interstitial pneumonia, pulmonary arteries become thickened with medial hypertrophy but features of idiopathic pulmonary hypertension, such as plexiform lesions, are not seen.^{126,181-183} Cigarette smokers have a lower incidence of HP than never smokers; nonetheless, smokers who do develop HP have a poorer outcome than nonsmoking counterparts.¹⁸⁵

The pathologic differential diagnosis for HP depends on the histologic features of a given case. Cases with all classic histologic and clinical features offer a straightforward diagnosis. In cases of chronic HP that lack granulomas, distinction from other patterns of ILD such as UIP, NSIP, LIP, COP, or bronchiolocentric interstitial pneumonia may be difficult. The centrilobular distribution of the fibrosis or cellular infiltrate may favor HP over UIP, NSIP, or LIP. The presence of significant fibrosis or cellular inflammation should distinguish HP from COP. In the absence of granulomas, clinical features and exposure history may be required to separate HP from bronchiolocentric interstitial pneumonia.^{102,103,155,178,181}

In cases with granulomas, the differential diagnosis includes infections, sarcoidosis, and aspiration. Infectious granulomas more frequently appear to be “floating” in air spaces and may disclose organisms with special stains; the granulomas of HP are located within the interstitium. In sarcoidosis, the granulomas are well-formed and are associated with less interstitial cellular inflammation than typically seen in HP. The discovery of foreign material, especially food or tablet fragments, may help reveal the source of a granulomatous pneumonitis to be aspiration induced. HP is bilateral and often upper lobe predominant whereas aspiration may involve the lower lobes, especially the right lower lobe. Therefore, the clinical and radiologic context may help guide the pathologic diagnosis, especially if foreign material or acute pneumonia is not seen on a small biopsy.^{116,186}

Sarcoidosis

Sarcoidosis is an idiopathic multisystem disorder that frequently affects the lungs and hilar lymph nodes; however, any organ system can be involved. Women are affected more frequently than men with the highest incidence worldwide in northern European countries. In the United States, sarcoidosis is most common in African Americans with an incidence of 35.5 per 100,000 people versus 10.9 per 100,000 Caucasians.¹⁸⁷ The peak incidence varies among different ethnicities but overall tends to affect younger patients in the third to fifth decade of life. A thorough discussion on the demographics, clinical features, and proposed etiology is found in Chapter 66.

The clinical and radiographic features of sarcoidosis are dependent upon the organ systems involved and the stage of the disease. Nonspecific symptoms include fever, weight loss, lethargy, myalgia, arthralgia, and dry eyes with blurry vision. Pulmonary symptoms include dyspnea, dry cough and, in some cases, digital clubbing. Imaging studies reveal bilateral hilar and mediastinal adenopathy (see Fig. 66-3), perilymphatic micronodules (see Figs. 18-24, 66-4, and 66-5), and upper lobe-predominant bilateral reticular opacities (see Fig. 66-6) in up to 15% of patients.¹⁸⁸⁻¹⁹¹

Grossly, lungs with sarcoidosis may reveal diffuse interstitial fibrosis with honeycomb changes in the worst affected

areas. Small pale millimeter sized nodules representing granulomas often may be seen throughout the lungs and on the pleural surfaces (Fig. 14-28A). Hilar lymph nodes may be markedly large, firm, and pale.

Histologically, the cardinal feature of sarcoidosis is the presence of numerous nonnecrotizing granulomas that are well formed and consist of clusters of multinucleated giant cells with admixed epithelioid histiocytes. Giant cells may contain asteroid bodies, Schaumann bodies, calcium oxalate, or carbonate crystals and Hamazaki-Wesenberg bodies. The granulomas may coalesce and form nodules of fibrosis, so-called nodular sarcoid. Granulomas are distributed along lymphatic channels and are frequently found in the bronchovascular bundle, on the pleural surface, and in the interlobular septa and diffusely throughout the hilar lymph nodes (see Fig. 14-28B-C). The location of granulomas in and around airways allows for high degree of diagnostic accuracy by transbronchial biopsy with up to 90% sensitivity.^{192,193} Punctate necrosis may be seen in up to one third of cases but special stains for organisms and cultures must be negative. There is relatively sparse interstitial chronic inflammation. All of these findings are nonspecific and require careful pathologic and clinical evaluation to rule out other forms of granulomatous pneumonitis.^{186,194,195} Sarcoidosis and common variable immunodeficiency: similarities and differences.^{195a}

Nonnecrotizing granulomatous vasculitis is seen in up to two thirds of open lung biopsy specimens. The involved vessel walls contain multinucleated giant cells or epithelioid granulomas. Fibrinoid necrosis of vessels and acute neutrophilic inflammation are not seen in sarcoidosis.¹⁸⁶

In up to 15% of patients, the pulmonary disease progresses and may result in extensive interstitial fibrosis with honeycombing and cystic changes. The fibrosis extends out from lymphatic areas and may resemble a UIP-pattern of fibrosis. However, the fibrosis has a temporally uniform appearance and fibroblastic foci are not conspicuous. Non-invasive aspergillomas or other fungus balls may grow in the cystic spaces with the risk of development of invasive fungal disease (see Fig. 38-3), if the patient becomes immunocompromised. As the fibrosis increases, the concentration and number of granulomas may decrease. In some cases of advanced end-stage pulmonary fibrosis, there may be no identifiable granulomas on pathologic evaluation.¹⁸⁶

The differential diagnosis encompasses many granulomatous diseases in the lungs; considerations include infection, hypersensitivity pneumonitis, drug reaction, and reaction to exogenous materials such as beryllium and talc. Clinical and microbiologic studies can exclude most entities in the differential diagnosis. In HP, granulomas are poorly formed and the process is usually associated with more prominent cellular interstitial inflammation. However, pulmonary involvement by beryllium disease may be identical to sarcoidosis, and only exposure history and/or the beryllium lymphocyte stimulation test can distinguish the two entities.¹⁹⁶

Pulmonary Langerhans Cell Histiocytosis

Pulmonary Langerhans cell histiocytosis (PLCH) describes a proliferation of Langerhans cells and has been described in multiple locations including the skin, lymph nodes, bones, and lungs. In extrapulmonary locations, the Langerhans

Figure 14-28 Sarcoidosis. **A**, Gross image shows numerous nodules on pleural surface corresponding to nodular sarcoid. **B**, Well-formed epithelioid granulomas in paucicellular fibrotic background. (H&E stain; original magnification $\times 200$.) **C**, Hilar lymph node with innumerable coalescing epithelioid granulomas. (H&E stain; original magnification $\times 100$.)

cell proliferation is clonal and likely a neoplastic process, usually affecting children or young adults.¹⁹⁷ In PLCH, the disease is usually associated with smoking and is most often a reactive process. The peak incidence is in young adult smokers, and the disease may remit with cessation of smoking if prominent fibrosis has not yet developed.

Clinically, patients may complain of cough, dyspnea, weight loss, and fever and are at increased risk of spontaneous pneumothorax. Radiographic studies reveal bilateral reticulonodular opacities most prominent in the midzones. As the disease progresses, the nodules become more cystic and can involve all lung zones (see eFig. 54-37).^{198,199}

Pathologically, the earliest stage of disease has multiple centrilobular stellate nodules of cellular infiltrates of Langerhans cells, eosinophils, lymphocytes, and histiocytes (Fig. 14-29A-B). The identification of clusters of Langerhans cells confirms the diagnosis. Langerhans cells have pink granular cytoplasm with vesicular, beanlike nuclei and are highlighted by CD1A (see Fig. 14-29C) and S100 immunohistochemistry staining. Initially, lesions appear rounded, but as the disease progresses, stellate-shaped fibrotic scars slowly replace the cellular infiltrates until only few inflammatory cells remain (see Fig. 14-29A). Later stage PLCH can be diagnosed by the stellate shape and centrilobular location of the scars in association with the characteristic

radiographic findings and clinical history of smoking. The infiltrate and scarring of PLCH can result in small airway obstruction and distal acinar air-trapping that may lead to the development of a pneumothorax. In severe cases of PLCH, the upper and midzone predominant pulmonary fibrosis can progress to honeycomb changes and end-stage fibrotic lung disease, resulting in a need for lung transplantation.^{159,200,201}

Lymphangioleiomyomatosis

Lymphangioleiomyomatosis (LAM) is a rare disease of abnormal smooth muscle cell proliferation found almost exclusively in woman of reproductive age. LAM is seen sporadically or as a complication of tuberous sclerosis. Patients usually present with dyspnea and are prone to hemoptysis, chylous effusions, and pneumothoraces. Imaging studies show enlarged lung fields with diffuse thin-walled cystic changes throughout all lung zones and may be diagnostic if the patient has clinical features of LAM (see Fig. 18-29).

The gross appearance reveals large lungs with diffuse replacement of the parenchyma by thin-walled cysts throughout all lobes (Fig. 14-30A). Microscopically, the lung shows multiple cysts as well innumerable foci of irregular smooth muscle cell aggregates in the walls of alveoli and bronchioles in all parts of the lung and within thoracic

Figure 14-29 Pulmonary Langerhans cell histiocytosis (PLCH). **A**, A stellate shaped infiltrate of inflammatory and histiocytic cells expands the interstitium. (H&E stain; original magnification $\times 40$). **B**, This sheet of Langerhans cells shows a moderate amount of eosinophilic cytoplasm with nuclei showing prominent characteristic grooves (arrow). (H&E stain; original magnification $\times 800$). **C**, The Langerhans cells stain strongly with CD1a. (Immunohistochemistry for CD1a; original magnification $\times 200$.)

Figure 14-30 Lymphangioleiomyomatosis (LAM). **A**, Gross image shows numerous thin-walled cysts evenly distributed throughout entire lung parenchyma. **B**, Collection of abnormal cluster of smooth muscle cells in wall of respiratory bronchiole. (H&E stain; original magnification $\times 200$). **C**, Immunostain highlights diffuse infiltration of clusters of smooth muscle cells throughout parenchyma and expression of HMB-45 (arrow). (Immunohistochemistry for HMB45; original magnification $\times 200$.)

lymph nodes (see Fig. 14-30B-C). These cells arise from a somatic cell mutation and are actually a mesenchymal tumor. The smooth muscle aggregates result in obstruction of airways and lymphatic vessels that cause cystic dilatation and lymphatic obstruction distal to the lesion. The smooth muscle cells appear small with higher nuclear to cytoplasmic ratios than normal and may be spindle shaped or epithelioid with bland cigar-shaped nuclei. Along with other smooth muscle cell markers, LAM also expresses HMB-45 (see Fig. 14-30C) as well as estrogen and progesterone receptors. HMB-45 expression is a common feature of a rare category of tumors known as “perivascular epithelioid cell” class of tumors (PEComas). PEComas are mesenchymal tumors composed of clear epithelioid cells and are more commonly found in women. LAM and renal angiomyolipomas are the most common type of PEComas. LAM and other PEComas are often found in the setting of tuberous sclerosis but may also arise sporadically.^{196,202-204} Additional information on LAM can be found in Chapter 69.

Eosinophilic Pneumonia

Eosinophilic pneumonia (EP) represents a spectrum of disease from a mild transient process to severe interstitial fibrosis. In most cases, patients have peripheral eosinophilia that, when coupled with infiltrates on imaging studies, leads to the diagnosis. EP may be an idiopathic process or may be secondary to numerous other processes.

Both idiopathic and secondary forms of EP can be categorized into simple, acute, or chronic EP. Simple EP, also called Löffler syndrome, is characterized by very high but transient peripheral eosinophilia and migratory pulmonary opacities. Many patients are asymptomatic but others have dry cough and dyspnea. Many patients may ultimately demonstrate infection with *Ascaris* but idiopathic cases are seen. Due to the classic clinical and radiologic features, cases are rarely biopsied. Nevertheless, lung biopsies may show numerous eosinophils in the alveolar space and interstitium.¹⁹⁶

Acute EP is a sudden onset disease process that presents with cough, fever, dyspnea, and pleuritic chest pain and may lead to acute respiratory distress syndrome. Acute EP may be seen at any age and sexes are affected equally. Blood may have elevated or normal eosinophil levels but BAL fluid usually has more than 25% eosinophils. Imaging studies show the diffuse opacities characteristic of acute respiratory distress syndrome (see eFig. 68-4). Pathology demonstrates acute lung injury with accompanying tissue eosinophilia (Fig. 14-31). Fortunately, most cases respond quickly to corticosteroid treatment, which may eradicate the eosinophils after the first dose, making pathologic diagnosis difficult if the biopsy was performed after initiation of treatment. Nevertheless, in the appropriate clinical setting, the diagnosis of “compatible with partially treated/resolving acute eosinophilic pneumonia” may be rendered if the biopsy reveals acute lung injury/DAD only.²⁰⁵

Chronic EP is an insidious process that progresses for several months before presentation. Most patients are women with a peak incidence in the fifth decade and many have a history of asthma or other atopic illness. Symptoms include cough, dyspnea, fevers, and weight loss. Eosinophils are often very high in the blood and BAL fluid. Chest radiographs demonstrate consolidation in bilateral subpleural

Figure 14-31 Eosinophilic pneumonia (EP). This area of acute lung injury has a florid infiltrate of eosinophils throughout the alveolar spaces and the interstitium. (H&E stain; original magnification $\times 200$.)

lung regions, a finding that has been called “reverse pulmonary edema pattern” (see eFigs. 68-1 and 68-3 and Video 68-1).²⁰⁶

Pathologically, eosinophils are clustered in alveolar spaces along with alveolar macrophages and may form small abscesses with central necrosis (see Figs. 68-1 through 68-3). In idiopathic cases, stain for organisms and culture results are negative. There may be occasional sarcoid-like granulomas and vascular inflammation but there are no lesions of necrotizing vasculitis. The pathologic hallmark of chronic EP is the presence of interstitial fibrosis, which can progress and become extensive with honeycomb changes. The fibrosis may resemble UIP or fibrotic NSIP patterns. As with acute EP, the eosinophils in chronic EP respond well to corticosteroid treatment and may become scarce after initiation of treatment. The clinical context and history of blood or BAL eosinophilia may aid in the recognition of the correct diagnosis.^{196,205-207} More information on eosinophilic lung is found in Chapter 68.

An expanded discussion of various forms of vasculitis and pulmonary hypertension is available online at *ExpertConsult*.

Key Points

- The evolution in our understanding and treatment of lung cancer now necessitates the use of specific pathologic diagnoses. The combination of morphologic features and judicious use of immunohistochemistry stains should be used to classify the type of carcinoma.
- Adenocarcinomas may have identifiable driver mutations that can represent therapeutic targets. When examining small biopsy specimens, it is important to be judicious in the use of immunohistochemistry analysis to preserve material for subsequent molecular and cytogenetic analysis. The recommended minimum molecular analysis of lung adenocarcinoma is an investigation for *EGFR* mutations and for *ALK* translocations.
- The classification of adenocarcinoma is based on the size of the pathology specimen and the predominant

VASCULITIS

Vasculitis is inflammation in a vessel wall and may be primary (idiopathic) or secondary. The idiopathic vasculitides that most commonly affect the lungs are *granulomatosis with polyangiitis* (GPA), formerly Wegener granulomatosis, *eosinophilic granulomatosis with polyangiitis* (EGPA), or Churg Strauss syndrome, and microscopic polyangiitis. The vasculitides share several clinical and radiographic features and may be distinguished by laboratory data, especially serologic studies, and pathologic findings. All three vasculitides are associated with abnormal autoimmune circulating antibodies termed ANCA (*antineutrophil cytoplasmic antibodies*) which affect small and medium-size blood vessels, often present with hemoptysis, and often have concurrent involvement of the kidneys, resulting in pulmonary renal syndrome. Other sites may also be involved, including the upper respiratory tract, skin, gastrointestinal tract, and the musculoskeletal and nervous systems.²⁰⁸⁻²¹⁰

The pathophysiology and clinical features of the various vasculitides are reviewed in more detail in Chapter 60.

GRANULOMATOSIS WITH POLYANGIITIS

GPA is a rare disease characterized by a triad of necrotizing granulomatous vasculitis in the upper respiratory tract, lower respiratory tract, and kidneys, resulting in bloody nasal discharge, hemoptysis with respiratory distress, and acute renal failure, respectively. Frequency of involvement is 90% for the upper and lower respiratory tract and 80% for the kidneys. GPA is usually associated with cytoplasmic type ANCA (c-ANCA) in contrast to the other two ANCA-associated vasculitides.²¹¹

Radiographic studies reveal multiple and bilateral lung masses that frequently cavitate and may be found in all lung zones but are most frequent in the lower lobes (see eFigs. 60-1 and 60-2). Pathologically, the lesions are composed of irregularly shaped, or “geographic,” necrosis that is usually basophilic (eFig. 14-1A; see Fig. 60-5). Small to medium sized vessel with transmural fibrinoid necrosis may be found in the lesions of geographic necrosis. There is an ill-defined granulomatous reaction of epithelioid histiocytes surrounding the inflamed vessels with scattered multinucleated giant cells with dark or basophilic cytoplasm that sometimes appear small. Alveolar capillaries may have capillaritis with engorgement of neutrophils and karyorrhectic debris (see eFig. 14-1B). Neutrophilic microabscesses rimmed by granulomatous inflammation and scattered multinucleated giant cells is a characteristic finding and does not indicate concurrent infection. Vascular injury may result in diffuse alveolar hemorrhage that can be difficult to distinguish from biopsy artifact. The presence of numerous hemosiderin-laden macrophages confirms authentic hemorrhage and discounts artifactual bleeding. Bronchioles may be involved or obliterated by the necrotizing granulomatous inflammation and, if larger airways are involved, the necrosis affects the cartilage. In older cases that have undergone repair, chronic vascular changes may be detected by identifying disruption of arterial internal elastic lamina through the aid of elastic tissue stains. The elastic layer shows abrupt disruption and fragmentation, and the

arterial intima may contain abnormal fibrosis with infiltration of mononuclear cells.²¹¹⁻²¹³

Immunofluorescence studies for evaluation of antibody deposition are very weak or negative and are only useful to rule out other entities in the differential diagnosis, such as immune complex-mediated vasculitis. Electron microscopy studies are not indicated.

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS

EGPA is a very rare disease defined by the presence of asthma, peripheral eosinophilia, and systemic vasculitis. The most common type of ANCA is perinuclear ANCA (p-ANCA) but c-ANCA is found in 10% of cases and 30% of cases have no identifiable ANCA. Pathologically, EGPA and GPA share many features but may be distinguished by the presence of numerous eosinophils in EGPA. As with GPA, vasculitis with palisading granulomatous inflammation, geographic necrosis, capillaritis, and diffuse alveolar hemorrhage may be seen (eFig. 14-2; see Fig. 68-6).^{205,213-215}

MICROSCOPIC POLYANGIITIS

Microscopic polyangiitis affects only small vessels and is not associated with granulomatous inflammation. It is associated with p-ANCA in 50% of cases, with c-ANCA in 40% of cases, or with no identifiable ANCA in 10% of cases. It is the most common cause of pulmonary-renal syndrome. The dominant pathologic feature is capillaritis with diffuse alveolar hemorrhage (eFig. 14-3). In this setting, immunofluorescence studies are useful to exclude other causes of diffuse alveolar hemorrhage such as Goodpasture syndrome, lupus pneumonitis, cryoglobulinemia, or other immune complex-mediated diseases.^{211-213,216,217}

PULMONARY HYPERTENSION

Pulmonary hypertension is a frequent complication of patients with underlying diffuse lung disease, left-sided heart disease, and chronic thromboembolic disease but is rare in the primary setting and usually affects young and middle-aged women. A full discussion of the clinical and pathophysiologic features of pulmonary hypertension is found in Chapter 58.

As described in Chapter 58 (see Table 58-1), pulmonary hypertension is classified into five clinical classes. Each group has subcategories and multiple etiologies.

The pathology of pulmonary arterial hypertension is graded on the severity of changes in the wall and increases as follows: pulmonary arteriopathy with isolated medial hypertrophy, pulmonary arteriopathy with medial hypertrophy and intimal thickening, pulmonary arteriopathy with plexiform and/or dilation lesions, and pulmonary arteriopathy with isolated arteritis. The plexiform lesion consists of a small focus of tightly intertwined slitlike vascular spaces lined by mildly swollen endothelial cells (eFig. 14-4). The surrounding lung may appear normal or have an increase in hemosiderin-laden macrophages. The plexiform lesions are often adjacent to dilated thin-walled vascular channels that balloon in response to the increased

pulmonary blood pressure associated with the plexiform lesion. The presence of numerous dilatation lesions indicates higher pathologic grade. In severe cases, the pulmonary hypertension can result in paucicellular necrosis of the vessel wall and necrotizing arteritis.^{196,219}

Plexiform lesions may mimic the changes associated with organizing thromboemboli but can be distinguished by several features. Plexiform lesions are found in small arteries or arterioles, whereas organizing thromboemboli often involve large or medium-sized pulmonary arteries. Plexiform lesions have slitlike channels, whereas organizing thromboemboli have larger and rounded channels. Finally, an elastin stain of plexiform lesions shows abnormal elastin, with small wisps of elastic tissue present between the slitlike spaces, whereas an elastin stain in organizing thromboemboli shows an intact internal elastic lamina.

Capillaries and pulmonary veins may also be the site of vascular obstruction. In pulmonary capillary hemangiomatosis, there is an increase in capillaries in alveolar walls, peribronchiolar tissue, pleura, and interlobular septa (eFig. 14-5A). The capillary proliferation may be demonstrated by a reticulin-collagen stain or endothelial cell marker such as CD31. In most cases, pulmonary capillary hemangiomatosis is accompanied by venous intimal thickening in interlobular septa, termed pulmonary veno-occlusive disease. The intimal thickening is due to fibrosis that is initially myxoid in character but eventually becomes denser and more collagenized (see eFig. 14-5B). There are often scattered mononuclear cells throughout the intima but no evidence of vasculitis.^{196,219,220}

subtype. Disease-free survival studies have shown the best prognosis for patients with adenocarcinoma in situ or minimally invasive adenocarcinoma.

- The diagnostic distinction between adenocarcinoma and squamous cell carcinoma is now important because of several therapeutic differences between the two pathologic types of non-small cell lung cancer.
- The most recent classification of *idiopathic interstitial pneumonias* (IIPs) divides the main diseases into four categories: *fibrosing interstitial lung disease* (ILD), acute/subacute ILD, smoking-related ILD, and rare IIPs.
- The most common pattern of fibrosing ILD is usual interstitial pneumonia, followed by nonspecific interstitial pneumonia. All patterns of ILD may be primary or secondary. Careful clinical, radiologic, and pathologic correlation is required to determine the underlying etiology.
- The differential diagnosis of *granulomatous pneumonitis* includes sarcoidosis, hypersensitivity pneumonitis, infections, drug-reaction, and chronic aspiration.

Cells Involved in Lung Repair

GENE-ENVIRONMENT INTERACTIONS IN LUNG INJURY AND REPAIR**DOES LUNG REPAIR RECAPITULATE LUNG DEVELOPMENT?****INTRODUCTION**

The pathogenesis of many pulmonary diseases involves the processes of lung injury and repair, and indeed maintenance of normal lung homeostasis involves cycles of ongoing subclinical microinjury and repair. Injury can be viewed at different levels from the context of whole-organ function or at the level of individual cells or molecules. Similarly, repair can be considered at several levels. Repair can be considered as a sequence of pathologic processes as in repair of a skin wound, at the level of cell replacement, at the level of patching of holes in plasma membranes, or at the level of molecules broken down in the proteasome and replaced by *de novo* synthesis. Given the complexity of these processes, we provide our definition of the terms *injury* and *repair* with the aim of limiting what would otherwise be an exhaustive discussion. In this chapter we will focus on the cellular injury resulting in the dysfunction or death of cells that underlies the pathogenesis of many pulmonary diseases. Injury to any of the different cell types residing in the lung can ultimately lead to organ dysfunction (for a review of lung structure, see Chapter 1). A broad concept of lung repair includes processes by which the function of the injured lung is restored to normal. In regard to reparative processes, we will focus on the cellular aspects of repair, including replacement of destroyed cells and restoration of normal cellular function.

LUNG INJURY AND REPAIR DURING HOMEOSTASIS

As a major portal to the environment, the lung is continuously exposed to a vast array of chemical and biologic agents that can cause cellular dysfunction or even death. Acute episodes of injury to the lung, as a result of viral infection or chemical exposures, result in transient alterations in lung function. *Repair* therefore can be defined as restitution of the cells, and thus of the lung, to the preinjury level of structure and function. Normal repair returns the lung to a healthy state that is capable of responding to subsequent injuries. The response of the lung to repeated

injury and repair is shown in [Figure 15-1](#). Normal aging is manifest by steady and progressive declines in cell number and/or function and in overall lung function ([Fig. 15-1](#), straight blue line), in part due to episodes of recurrent microinjury and decreased capacity of the epithelium or endothelium to heal itself. Normal repair can return the lung function to its prior state ([Fig. 15-1](#), fluctuating blue line). Faulty repair leads to episodic loss of function that ultimately results in respiratory failure ([Fig. 15-1](#), orange line).

LUNG INJURY AND REPAIR DURING DISEASE

Many common pulmonary disorders, such as *chronic obstructive pulmonary disease* (COPD), interstitial lung disease, asthma, cystic fibrosis, and the *acute respiratory distress syndrome* (ARDS), are characterized by cellular injury and faulty repair resulting in clinically significant physiologic abnormalities. The intensity and duration of the insult contribute to the time of onset of symptoms and the chronicity of disease. In ARDS, a severe insult causes widespread lung injury and respiratory failure in hours to days. By contrast, in COPD, years of exposure to the offending agent (usually cigarette smoke in the developed world and biomass fuels in developing countries) results in slowly progressive loss of respiratory function. Patients with interstitial lung disease often have a stuttering course with periods of rapidly declining lung function interspersed with periods of relative quiescence. Importantly, in addition to injury, dysfunctional repair and “remodeling” contribute to the pathogenesis and clinical course of lung diseases, including COPD, asthma, interstitial lung disease, and fibroproliferative ARDS.

LUNG INJURY

The pathogenesis of many lung diseases involves an exogenous (e.g., inhaled toxin, allergen, infectious agent) or endogenous (inflammation or autoimmune) agent causing cellular dysfunction or death. In COPD, inhaled toxins such as those that make up cigarette smoke initiate processes

Figure 15-1 Conceptual relationship between lung function and time.

Normal aging can be viewed as a process in which steady and progressive declines in cell number and/or function reflect parallel decrements in the capacity of the epithelium or endothelium to heal itself (straight blue line). Acute episodes of injury to the lung and its cellular and structural components, such as viral infection or chemical exposures, result in temporary fluctuations in lung function (fluctuating blue line). Chronic lung disease is associated with a progressive loss of lung function that is exacerbated by environmental exposures. Individuals affected by chronic lung disease may be predisposed to repeated episodes of lung injury and may undergo cycles of injury that result in an accelerated decline in lung function (orange line). Once a hypothetical functional threshold is reached (red line), the lung may no longer have the capacity to repair itself and functionality is irreversibly lost. (Adapted from Lazaar AL, Panettieri RA Jr: Is airway remodeling clinically relevant in asthma? *Am J Med* 115:652–659, 2003.)

that culminate in epithelial and endothelial cell death,^{1–5} as well as destruction of extracellular matrix, the scaffolding of the lung.⁶ In asthma, allergens, environmental pollutants, pathogens, and the inflammatory response to these agents induce injury to the bronchial epithelium.^{7–9} Pulmonary fibrosis is thought to reflect repetitive injury to the lung epithelium interspersed with periods of relative quiescence.^{10,11}

To illustrate the processes involved in lung injury, we will focus on inflammatory lung injury in ARDS. An extensive review of the causes, pathogenesis, clinical manifestations, and treatment of ARDS is included in Chapter 100. Briefly, ARDS is defined as the acute onset (within 1 week of the inciting event) of hypoxemia and bilateral opacities on chest imaging attributable to noncardiogenic (increased permeability) pulmonary edema. The severity of ARDS is graded according to the ratio (“P/F ratio”) of the partial pressure of oxygen in the arterial blood to the fractional concentration of oxygen in the inspired air, with a P/F ratio of 200 to 300 defined as “mild,” 100 to 200 defined as “moderate,” and less than 100 defined as “severe.”¹² ARDS is a heterogeneous syndrome rather than a single disease, and predisposing causes include pneumonia, extrapulmonary sepsis, inhalational injury, aspiration, injurious (high tidal volume) mechanical ventilation, pancreatitis, trauma, and blood transfusion. In addition to the acute medical condition, risk factors for the development of ARDS include acquired disorders such as alcohol abuse¹³ or cigarette smoking¹⁴ and genetic determinants such as certain genetic polymorphisms^{15–34} (Fig. 15-2). Treatment

Figure 15-2 Acute lung injury (ALI): clinical risk factors. Based on the results of several epidemiologic studies published over the last 2 decades, a variety of factors have been identified that can alter the susceptibility of an individual patient to the development of ALI. These factors can be separated into three general categories: genetic determinants, preexisting acquired disorders, and the acute medical condition. The identification of such patient-specific characteristics could significantly improve both our understanding of the pathogenesis of ALI and our ability to care for these critically ill patients.

of ARDS is mainly supportive and includes lung protective (low tidal volume) mechanical ventilation³⁵ and a conservative fluid management strategy.³⁶

Epithelia and endothelia form selective barriers separating various body compartments of different composition from each other or the body from the environment. This barrier function depends on the presence of an intact layer of viable cells as well as the intercellular junctions that link adjacent cells, thus restricting the movement of fluid, ions, and macromolecules. In the healthy lung, the epithelium due to its tight intercellular junctions is the major barrier for passive fluid leak into the alveolar spaces, and, in addition, there is active fluid removal from the alveolar space via the action of specialized ion pumps and transporters in the epithelial cells. In ARDS, compromise of the selective barriers, epithelial as well as endothelial, either via disassembly of intercellular junctions or via death and sloughing of cells, results in an increase in lung permeability and the influx of protein-rich edema fluid,^{37,38} which leads to refractory hypoxemia and bilateral infiltrates on chest radiographs.^{39–42} Cellular dysfunction, such as impaired fluid transport^{43,44} and decreased surfactant production,^{45,46} further contributes to the impaired lung compliance and gas exchange abnormalities.

In ARDS, epithelial and endothelial injury is largely attributable to excessive and dysregulated inflammation^{41,47} (Fig. 15-3) (see Chapter 100). In the case of pneumonia, the most common cause of ARDS, microbial products are recognized by resident lung cells, which in turn secrete chemoattractants that recruit inflammatory cells, initially neutrophils, into the lungs.^{48–52} Chemoattractants stimulate neutrophil actin assembly, resulting in stiffening and retention of neutrophils in the pulmonary capillaries.⁵³ This is followed by intercellular adhesion molecule-mediated adhesion to the endothelium,^{54–56} a process that requires heparanase-mediated cleavage of the glycocalyx,⁵⁷ egress from the bloodstream,⁵⁸ and transmigration across the epithelium into the air spaces.⁵⁹ Neutrophils contain potent

Figure 15-3 Electron micrograph of inflammatory injury in the murine lung. A key contributor to lung injury, from either the vascular or epithelial surface, is the inflammatory process, including the effects of inflammatory mediators and the accumulation and activation of inflammatory cells. This electron micrograph depicts damage to endothelial and alveolar epithelial cells accompanying sequestration and activation of neutrophils in an acute inflammatory response. The process is usually associated with increased vascular and alveolar permeability, sometimes with sufficient damage to the alveolar wall to result in coagulation (fibrin) and erythrocyte accumulation in the air spaces. RBC, red blood cell.

antimicrobial compounds, including oxidants, proteinases, and cationic peptides. During immune surveillance or a normal immune response, neutrophils ingest (phagocytose) microorganisms and release these antimicrobial compounds directly into the phagosome.⁶⁰ Neutrophil influx into the lungs under most circumstances does not result in tissue injury.^{61,62} However, during excessive and dysregulated inflammation in ARDS, large numbers of activated neutrophils release proteolytic enzymes and oxidants into the extracellular space, causing tissue injury.^{59,63,64} For example, neutrophil elastase, although inherently antimicrobial and critical for host defense,^{65,66} has been shown to cause injury not only to the extracellular matrix in COPD^{67,68} but also to the alveolar capillary membrane in ARDS.⁶⁹⁻⁷⁶ Importantly, neutrophil elastase can cause both a disruption of intercellular junctions^{77,78} and death of endothelial⁷⁹⁻⁸¹ and epithelial^{82,83} cells. ARDS patients have elevated levels of elastase in their bronchoalveolar lavage fluid and plasma, and these levels correlate with the severity of lung injury.⁸⁴⁻⁸⁷ Unfortunately, pharmacologic agents that inhibit neutrophil elastase have not proven to be effective in the treatment of ARDS.^{88,89}

In addition to neutrophil elastase, other serine proteases, *matrix metalloproteinases* (MMPs) and cysteine proteinases are released by inflammatory cells and contribute to tissue destruction during lung injury.⁶⁹ Increased levels of MMPs,

derived from both neutrophils and macrophages, are present in patients with ARDS⁹⁰⁻⁹⁴ and contribute to lung injury.⁹⁵⁻¹⁰⁰ The mechanisms by which MMPs cause lung injury have not been fully elucidated. They are known to degrade junctional proteins in both epithelial¹⁰¹⁻¹⁰³ and endothelial cells^{104,105} and induce cell death,¹⁰³ although the latter is dependent on the cell type and specific MMP. Conversely, some MMPs promote survival of the lung epithelium,¹⁰⁶ and others may attenuate injury¹⁰⁷ or even promote repair.^{108,109}

Defensins are cationic peptides released from inflammatory cells that have potent antimicrobial properties. As with other inflammatory mediators, defensins are released into the extracellular space in ARDS¹¹⁰ and can cause lung injury,^{111,112} including endothelial¹¹³ and epithelial¹¹⁴⁻¹¹⁷ cell death and noncytotoxic injury.¹¹⁸ Similar to proteinases, in certain contexts, defensins may also promote lung repair.^{119,120}

In addition to proteinases and antimicrobial peptides, oxidants, including reactive oxygen and nitrogen species, are released by inflammatory cells during ARDS¹²¹⁻¹²³ and contribute to tissue injury,¹²⁴⁻¹³² including epithelial¹³³⁻¹⁴¹ and endothelial^{142,143} cell death and disruption of tight junctions.¹⁴⁴⁻¹⁴⁶ Although the lung possesses potent endogenous antioxidant mechanisms, which serve to limit injury,¹⁴⁷⁻¹⁵⁵ in ARDS these mechanisms are overwhelmed by the large amount of reactive species generated. Additionally, oxidants can potentiate proteinase-induced lung injury, in part by inactivating antiproteinases.¹⁵⁶ Finally, lipid mediators¹³² and another recently recognized antimicrobial weapon, neutrophil extracellular traps, can cause epithelial and endothelial injury.¹⁵⁷⁻¹⁶⁰

Although much of the early injury to the alveolar capillary membrane is attributable to neutrophils (polymorphonuclear leukocytes) and their mediators,^{59,161-163} polymorphonuclear leukocytes cannot be the only perpetrators of lung injury because ARDS can develop in neutropenic patients.¹⁶⁴ Recruitment of monocytes to the lungs follows the initial neutrophilic response in ARDS.¹⁶⁵ In contrast to resident alveolar macrophages, which tend to have anti-inflammatory functions,^{165a} recruited macrophages secrete proinflammatory mediators, including cytokines, chemokines, and lipids, that propagate the inflammatory response. Recruited macrophages also release toxic mediators, including reactive oxygen and nitrogen species,^{166,167} MMPs,^{93,98,99,168} *tumor necrosis factor* (TNF)- α ,¹⁶⁹ vascular endothelial growth factor,¹⁷⁰ and interferon- β ,¹⁷¹ which may enhance host defense but also induce tissue injury.^{172,173,173a} In addition, recruited macrophages also play a critical role in both tissue repair¹⁷⁴⁻¹⁷⁶ and the resolution of inflammation^{177,178} (see later). The role of macrophages in lung inflammation, injury, and repair is further reviewed in Chapter 12. Finally, in addition to neutrophils and macrophages, platelets,¹⁷⁹ coagulation factors,^{56,180} products of infectious agents,¹⁸¹ inhaled toxins,¹⁸² oxygen,¹⁸³ and mechanical forces^{184,185} all can contribute to injury to the alveolar capillary membrane. Indeed, a diverse array of mechanisms, mediators, and signaling pathways has been implicated in lung injury.^{94,186-194} Because the spectrum of injurious agents in ARDS is so broad, it is not surprising that pharmacologic strategies to block a single pathway or class of mediators have been ineffective.

Having reviewed the pathogenic agents that induce lung injury, we will now focus on exploring what constitutes lung injury. As mentioned earlier, we define injury as cellular dysfunction or death. Although cellular dysfunction in ARDS includes impaired production of surfactant,¹⁹⁵ which is critical for lung compliance and important in host defense,¹⁹⁶ we will focus here on the cellular dysfunction and death that contribute to increased lung permeability. In inflammatory lung injury the cellular dysfunction that contributes to edema formation includes (1) disruption of intercellular junctions that are responsible for maintaining the barrier function of the endothelium and epithelium and (2) impaired active fluid transport that is responsible for fluid reabsorption and maintenance of dry air spaces. Transient opening and closing of intercellular junctions is necessary for the transmigration of immune cells during immune surveillance or during a normal immune response¹⁹⁷ and can take place without compromising barrier function.⁶² However, in ARDS, intercellular junctions of the endothelium^{144,198-201} and epithelium^{77,146} are disrupted, resulting in enhanced paracellular permeability, which contributes to the flooding of the alveolar spaces with edema fluid. This alveolar flooding is exacerbated by impaired function of the epithelial Na^+/K^+ pumps and epithelial Na^+ channels that are responsible for fluid reabsorption.²⁰²⁻²⁰⁸ Attempts at stimulating fluid clearance with β -agonists have not improved outcomes in ARDS,²⁰⁹ perhaps because the barrier must be restored before the pumps can be effective (see Chapter 9).

In addition to the disruption of intercellular junctions, severe lung injury in ARDS and other lung diseases^{5,210-212} is characterized by cell death. In ARDS, inflammatory mediators induce death of endothelial cells²¹³ as well as *alveolar epithelial type I* (ATI) cells, leaving surviving *alveolar epithelial type II* (ATII) cells, which are more resistant to injury, populating a largely denuded basement membrane.^{38,214-217} This dramatic injury to the alveolar epithelium engendered the term *diffuse alveolar damage*,²¹⁸ which describes the histologic appearance of lungs taken from patients who died of ARDS.

Endothelial and epithelial cells can be lost via necrotic cell death or via programmed cell death, the latter termed “apoptosis.” Originally a morphologic definition, apoptosis might best be defined not only on the basis of nuclear condensation and characteristic DNA fragmentation but also based biochemically on activation of intracellular proteases termed “caspases.” Many recent reviews address the various mechanisms underlying apoptosis.^{219,220} However, it is important to note that there are two major pathways leading to apoptosis: the intrinsic pathway, involving signaling from the mitochondria; and the extrinsic pathway, deriving from signals generated from external stimulation of “death” receptors. In “normal” adult humans or experimental animals, snapshot analyses of lung tissue indicate only small scattered examples of replicating cells or of cells undergoing apoptosis. Because apoptotic cells are actively extruded from epithelial surfaces and cleared rapidly, the fact that evidence of apoptosis is detectable at all may indicate a higher degree of cellular turnover than previously thought. Early reports suggested that mitochondrial regulation of alveolar epithelial apoptosis may be induced by the proapoptotic BCL2 family member BAX²²¹ and p53.²²² Additional literature suggests that death receptors of the

TNF receptor family such as FAS mediate apoptosis via the extrinsic pathway. Both FAS and FAS ligand levels are elevated in the edema fluid of ARDS patients, they induce epithelial cell apoptosis in a manner dependent on their modulation by oxidants and proteases, and elevated levels are predictive of worse clinical outcomes.²²³⁻²²⁵ In animal models of lung injury, FAS²²⁶ and TNF-related apoptosis-inducing ligand¹⁶⁹ induce epithelial cell apoptosis, and inhibition of apoptosis improves survival.²²⁷ Conversely, hyaluronan, while promoting inflammation, attenuates epithelial cell apoptosis.¹⁹¹ Apoptotic epithelial cells are engulfed by both professional phagocytes (macrophages) and other epithelial cells.^{228,229}

In ARDS, lung cells can also die by necrosis, which leads to disruption of cell membranes with subsequent release of cellular contents that may be injurious. Causes of epithelial and endothelial necrosis in ARDS include physical effects of acid from inspiration of stomach contents, inhalation of toxic materials or fumes, infection with lytic viruses or bacterial products, hyperoxia,²³⁰ and mechanical disruption of cell membranes during mechanical ventilation. In sum, cell death is a major mechanism of lung injury, resulting in denudation and contributing to lung permeability and the massive influx of edema fluid, despite the existence of endogenous protective mechanisms.

LUNG REPAIR

The ability of the lung to withstand considerable damage and repair itself enables recovery and survival from a variety of noxious stimuli.²³¹ For the purpose of this chapter, we define repair broadly as *processes by which the function of the injured lung is restored to normal*. Repair of the lung after acute injury requires restitution of the endothelial and epithelial barriers, clearance of edema fluid,²³²⁻²³⁷ and the resolution of inflammation.²³⁸ In the case of ARDS, survival depends on repair of the injured lung, although some survivors do not regain normal lung function.²³⁹

ENDOTHELIAL REPAIR

Given that lung injury involves disruption of intercellular junctions and cell death, repair requires repopulation of the denuded basement membrane and reassembly of these junctions. Elegant work has demonstrated the importance of sphingosine-1-phosphate, released from activated platelets, in stimulating reassembly of endothelial intercellular junctions via Rho- and Rac-dependent cytoskeletal rearrangement.²⁴⁰⁻²⁴² This process is dependent on $\alpha\text{v}\beta 3$ integrin.²⁴³ In addition, the SLIT/ROBO mechanism was recently identified to stabilize the endothelial adherens junctions by promoting p120-catenin/E-cadherin association.^{244,245} Stabilization of actin cytoskeleton by the Rho GTPases enhances endothelial barrier integrity.²⁴⁶ Additional information on the regulation of endothelial function is found in Chapter 6.

EPITHELIAL REPAIR

Although the alveolar epithelium is more resistant to injury than is the endothelium,²⁴⁷ increased epithelial permeability is required for the development of airspace edema.

Conversely, repair of the alveolar epithelium is critical for the resolution of edema, restoration of functions such as surfactant production and ion and fluid transport, and clinical outcome.^{202,248} In the epithelium, *keratinocyte growth factor* (KGF),¹⁴⁶ interferon- γ ,²⁴⁹ phosphatase and tensin homologue,²⁵⁰ epidermal growth factor,²³⁶ and c-Met²⁵¹ are protective of tight junctional integrity during lung injury by mechanisms that involve cytoskeletal reorganization rather than enhanced expression of junctional proteins.²⁵² Regulation of tight junctions in the alveolar epithelium after injury is an important and active area of investigation.²⁵³

If the severity of the injury is such that there has been extensive cell death, the endothelium and epithelium must be repopulated. As an illustration of the mechanisms involved, we will focus on re-epithelialization of the denuded alveolar epithelium after injury. The injured alveolar epithelium re-epithelializes in stages, many of which are orchestrated by the ATII cell, the “defender of the alveolus.”²⁵⁴ These stages include (1) ATII cell spreading and migration, (2) ATII cell proliferation, (3) differentiation of ATII cells into ATI cells to restore a normal constitution of the alveolar epithelium, and finally (4) if the injury is extensive, migration and proliferation of bronchiolar stem cells to repopulate the injured alveolus (Fig. 15-4; Video 15-1).

Recent work has identified various stem cell populations that likely contribute to this repair. Epithelial injury and repair promotes the activation of fibroblasts,^{255,256} which although important for physiologic wound repair, under certain circumstances, when dysregulated, can result in fibrotic lung disease. Each of these phenomena will be discussed in more detail in the following sections.

Cell Spreading and Migration

After death of alveolar epithelial cells, surviving ATII cells likely spread and migrate onto the denuded basement membrane. Although this has not been directly observed in the alveolar epithelium *in vivo*, cell spreading and migration is certainly the fastest mechanism for resealing the leaky epithelium²¹⁸ based on *in vitro* observations²⁵⁷⁻²⁵⁹ and on observations of the importance of these phenomena in wound repair of other organs.²⁶⁰ Cell migration depends on tightly regulated assembly of the cytoskeleton leading to protrusion of “lamellipodia” and “filopodia” from the leading edge followed by contractile forces that release the rear edge from the extracellular matrix, processes that depend on the Rho GTPases.^{261,262} In the lung epithelium, cell spreading and migration after injury are triggered by soluble factors such as KGF,²⁵⁹ transforming growth factor (TGF)- α ,²⁵⁸ TGF- β ,²⁶³ interleukin-1 β ,^{264,265} and

Figure 15-4 The injured alveolar epithelium re-epithelializes in stages. Alveolar epithelial type I cells (ATIs) are the most susceptible to injury. Surviving type II (ATII) cells spread and migrate onto the denuded basement membrane (BM), proliferate, and differentiate into ATI cells to restore a normal alveolar architecture. Meanwhile, active ion transport by the Na⁺/K⁺ ATPase, as well as passive ion uptake through ion channels (epithelial Na⁺ and cystic fibrosis transmembrane conductance regulator, not shown) creates an osmotic gradient. Water reabsorption follows through aquaporin channels. The resolution of inflammation depends on apoptosis of neutrophils followed by the uptake of apoptotic neutrophils by macrophages (“efferocytosis”), a process that is enhanced by transforming growth factor (TGF)- β released from T regulatory lymphocytes (Treg).

cytokine-induced neutrophil chemoattractant 2.²⁶⁶ Cell migration is further mediated by signaling pathways, including Rac1/TIAM1,²⁶⁷ phosphatase and tensin homologue,²⁶⁸ β -catenin,²⁶⁹⁻²⁷² syndecan-1,^{273,274} adenosine triphosphate and dual oxidase 1,^{275,276} and vimentin,²⁶³ as reviewed elsewhere.²⁷⁷ Integrins, which are up-regulated in the alveolar epithelium after injury,²⁷⁸ contribute to cell migration via interactions with both the actin cytoskeleton²⁷⁹ and the extracellular matrix.^{257,280-282} The production of extracellular matrix as well as MMPs are critical to cell migration.^{174,274} MMPs enhance wound healing by cleaving cell-cell and cell-extracellular matrix adhesion molecules, activating chemokines and growth factors by proteolysis, and degrading the provisional matrix.¹⁷⁵ Notably, cyclic stretch, imposed by mechanical ventilation during repair after ARDS, impedes cytoskeletal reorganization during cell spreading.²⁸³

Cell Proliferation

In addition to cell spreading and migration, the denuded epithelial basement membrane is repopulated through the proliferation of surviving ATII cells, which accounts for the epithelial cell hyperplasia observed on histologic samples.^{38,217,254,284} In animal models, significant acute lung injury resulting in cell death triggers alveolar epithelial cell proliferation.²⁸⁵ Factors that promote ATII cell proliferation after injury include the heparin-binding growth factors KGF, hepatocyte growth factor, and heparin-binding epidermal growth factor,²⁸⁶⁻²⁹² an effect that is significant enough to decrease mortality in animal models of lung injury,²⁹³ although the protective role of KGF may in part be attributable to enhanced epithelial cell survival.²⁹⁴ Other factors and pathways implicated in ATII cell proliferation after injury include granulocyte-macrophage colony-stimulating factor,^{295,296} which is also protective against injury,²⁹⁷⁻²⁹⁹ β -catenin signaling,^{300,301} macrophage migration inhibitory factor,³⁰² and FOXM1.³⁰³ Proliferating ATII cells ultimately differentiate into ATI cells^{236,285,304,305,305a} or die by apoptosis and are subsequently removed by macrophages or neighboring ATII cells.^{306,307} Mechanisms regulating differentiation of ATII cells into ATI cells are not well understood, but this process is promoted by TGF- β ³⁰⁸ and insulin-like growth factor-I.³⁰⁹ The classic concept has been that ATII cells are responsible for alveolar repair by spreading into the denuded area, proliferating, and ultimately differentiating into ATI cells. However, at least in vitro, transdifferentiation is reversible.³¹⁰ In this regard, a recent in vitro study reveals that ATI cells are also capable of cell spreading, migration, proliferation, and expression of surfactant protein-C,³¹¹ suggesting that these cells may also play a role in repair.

Role of Fibroblasts in Repair

Normal repair depends on epithelial-mesenchymal interactions, including the proliferation of subepithelial fibroblasts with deposition of granulation tissue. Mesenchymal cells provide signals and specific growth factors such as hepatocyte growth factor and KGF to epithelial cells to facilitate repair. By contrast, after repetitive and/or nonresolving injury, dysfunctional epithelial repair results in fibroblast recruitment, proliferation, and differentiation into myofibroblasts with deposition of excessive extracellular matrix

composed of collagen and fibronectin. Severe or repetitive epithelial injury with dysfunctional repair can promote fibroproliferative responses^{255,256,272,284,312-314} in ARDS^{38,40,315-317} and other lung diseases, including idiopathic pulmonary fibrosis,³¹⁸⁻³²⁰ asthma,^{7,8} and COPD,³²¹ a topic which is reviewed in detail elsewhere.^{11,322} Although cytokines and growth factors that induce physiologic repair can prevent fibrosis under certain circumstances,^{270,272,301,323,324} under other circumstances, these same factors may actually promote fibrosis,^{300,325-327} underscoring the importance of context in lung repair. Therefore caution is indicated when considering therapeutic intervention aimed at accelerating repair of the injured lung, so as not to induce fibrosis. Epithelial “regeneration,” the restoration of normal lung architecture, must be distinguished from “simple repair,” which can include repopulation by abnormal cell types and scar formation.³²⁸

Resolution of Inflammation

Ultimately, the inflammatory response must resolve in order to halt ongoing injury to the lung and allow reparative processes to proceed. An important step for resolution of inflammation is the apoptotic clearance of neutrophils. Neutrophils undergo apoptosis, a noninflammatory, non-immunogenic form of cell death during which they retain their toxic mediators within their plasma membrane. This is in contrast to a necrotic cell death, in which neutrophils disintegrate with release of their intracellular constituents, including toxic and proinflammatory mediators, resulting in prolongation of the inflammatory response. Neutrophil apoptosis can be delayed by proinflammatory mediators such as granulocyte-macrophage colony-stimulating factor and endotoxin³²⁹ and by hypoxia,^{330,331} but it is enhanced by T regulatory lymphocytes in a TGF- β -dependent manner.³³² Delayed neutrophil apoptosis is mediated by complex intracellular signaling pathways that involve hypoxia inducible factor-1³³¹ and cyclin-dependent kinases signaling through the antiapoptotic BCL2 family member MCL1.³²⁹ Apoptotic neutrophils are cleared by macrophages in a phagocytic process termed “efferocytosis” without release of toxic intracellular contents.^{177,178} Efferocytosis depends on the recognition of “eat me” signals, including phosphatidylserine³³³ and calreticulin,³³⁴ that are displayed on the apoptotic cell surface by a variety of receptors.^{335,336} This is followed by activation of Rho GTPases, leading to engulfment, which is regulated by the mitochondrial membrane protein UCP2,³³⁷ as well as HMGB1³³⁸ and urokinase-type plasminogen activator.³³⁹ Efferocytosis results in the release of anti-inflammatory mediators that further promote the resolution of inflammation³⁴⁰ rather than inducing a pro-inflammatory macrophage response. Apoptotic neutrophils can also be efferocytosed by myeloid-derived suppressor cells in an interleukin-10-dependent manner.³⁴¹ Whereas clearance of apoptotic neutrophils is usually highly efficient, yielding a low number of observable apoptotic cells at any given time,³⁴² if apoptotic clearance is defective or overloaded, apoptotic neutrophils can undergo secondary necrosis or postapoptotic cytolysis.³⁴³ Thus, impaired neutrophil apoptosis and efferocytosis would prolong the duration of the inflammatory response, likely resulting in chronic inflammatory lung disease.³⁴⁴ Lipid mediators promote the resolution of inflammation by enhancing

neutrophil apoptosis³⁴⁵ and efferocytosis,³⁴⁶⁻³⁴⁸ as well as through other mechanisms.³⁴⁹⁻³⁵² In addition to neutrophils, inflammatory macrophages must also be cleared during the resolution of lung injury.³⁵³

STEM CELLS, CONSTITUTIVE CELL TURNOVER, AND REPARATIVE CELL TYPES

HIERARCHIES OF REPARATIVE CELLS

The concept of injury and repair is fundamentally linked to the stem cell attributes of *mitotic potential* and *differentiation capacity*. Mitotic potential has two components, the number of times a cell can undergo division and the time at which these cell divisions take place. Differentiation potential is defined in terms of the variety of differentiated cell types that can be generated by an individual mitotic cell. Many of the current concepts about stem and progenitor cell function in the lung derive from studies of airway epithelial cells. Comparatively less is known regarding the identity of long-term stem cells in the alveolar region and even less is known about resident stem and progenitor cells for the diverse lung mesenchymal cell populations. The knowledge of the stem and progenitor cells' functions in the airway will be used as a foundation to illustrate the basic principles of how stem cells are involved in repair of the injured lung.

CLASSICAL STEM CELL HIERARCHY

Within a classical stem cell hierarchy (Fig. 15-5), the *stem cell* is defined as the reparative cell with the greatest mitotic and differentiation potential. A stem cell proliferates indefinitely and thus distributes its mitotic potential over the life span of the organism. These attributes of “stemness” are controlled by interaction of the stem cell with the *stem cell microenvironment or niche*. The niche serves to protect or sequester stem cells from factors that promote their differentiation. Stem cell division produces two daughter cells whose fate is determined by interactions with the stem cell niche. *Symmetrical cell division* results in both daughter cells retaining contact with the niche and maintenance of these nascent cells as stem cells. This mechanism, which results in amplification of stem cell number, has been demonstrated in tissues with rapid cell turnover, such as the bone marrow and gut. In contrast, *asymmetric cell division* results in generation of one daughter cell that maintains contact with the niche and is retained as a stem cell. The second daughter cell then loses contact with the niche and undergoes repeated cell division over a short period of time. This second daughter cell is the founding cell for the *transit-amplifying* cell population. Transit-amplifying cells are temporary constituents of the niche. They proliferate repeatedly over a short time period and then withdraw from the cell cycle as they commit to a differentiation pathway. Thus transit-amplifying cells serve to increase cell number and are destined to produce *terminally differentiated* cells. Terminally differentiated cells can have one or more phenotypes and constitute the majority of cells within a given tissue. These cells are largely responsible for conferring the

Figure 15-5 Classical stem cell hierarchy: stem cell, transit-amplifying cell, and terminally differentiated cell. Within a classical stem cell hierarchy, the *stem cell* is defined as the reparative cell with the greatest mitotic and differentiation potential. *Symmetrical cell division* results in both daughter cells retaining contact with the niche and retention of these nascent cells as stem cells. In contrast, *asymmetric cell division* (shown here) results in generation of one daughter cell that is retained as the stem cell and a second daughter cell that becomes the transit-amplifying cell. The transit-amplifying cell undergoes repeated cell division over a short period of time, ultimately producing *terminally differentiated* cells, which provide functions characteristic of a specific tissue. Terminally differentiated cells are postmitotic.

phenotypic characteristics of a specific tissue or organ. Terminally differentiated cells are postmitotic. Thus loss of the terminally differentiated cell population acts as a stimulus for the differentiation of transit-amplifying cells that resupply this population.

CELLS INVOLVED IN LUNG REPAIR

Progenitor Cell

The term *progenitor cell* is a collective term used to describe any cell that has the capacity to proliferate. It is commonly used to indicate a cell that is in the process of cell division or has the potential to enter the cell cycle. The functional distinctions among lung progenitor cells are defined in the sections that follow.

Tissue-Specific Stem Cells

A tissue-specific stem cell is a rare cell type that is undifferentiated relative to its progeny. This cell has the capacity for unlimited self-renewal as a consequence of stable interactions with a stem cell niche. In the context of a hierarchy, the stem cell is defined as the reparative cell with the greatest mitotic and differentiation potential. Adult tissue stem cells have a differentiation potential equivalent to the cellular diversity of the tissue in which they reside.³⁵⁴ Because

of the relatively quiescent state of the pulmonary epithelium, lung stem cells are identified as cells that are activated in response to severe cell depletion. As a consequence of this experimental approach, we will review the properties of lung stem cells in the context of severe injury.

Tracheobronchial tissue-specific stem cells have been evaluated in detail in mice. These cells exhibit a low cuboidal to pyramidal morphology and are termed *basal cells*. Additional studies have suggested that the tracheobronchial tissue-specific stem cell resides within specialized microenvironments located at the submucosal gland duct junction and in intercartilaginous regions of the trachea and bronchial epithelium.³⁵⁵ In murine bronchioles, tissue-specific stem cells have been identified within neuroepithelial bodies and bronchiolar duct junction microenvironments. These cells are resistant to club cell (Clara)-specific toxicants such as naphthalene and express the molecular marker *club cell secretory protein* (CCSP).³⁵⁶ The identity of alveolar stem cells remains incompletely understood. The ATII cell is generally believed to serve this function,^{305,357-360} although bronchiolar stem cell populations,^{305,358,359,361} which express $\alpha 6\beta 4$ integrin, keratin 5, or p63 but not prosurfactant C,³⁶² may function as alveolar epithelial progenitor cells after injury under certain circumstances.

Facultative Progenitor Cell Pools

A facultative progenitor cell is one that exhibits differentiated features in the quiescent state yet has the capacity to proliferate for maintenance of normal tissue and in response to injury. In contrast with the bone marrow and gut, the lung epithelium is maintained and repaired under most conditions by an abundant, broadly distributed facultative progenitor cell pool. Facultative progenitor cells exist in two states: quiescent and reparative. In the steady state, facultative progenitor cells are nonmitotic and carry out differentiated functions necessary for tissue homeostasis. In response to injury, facultative progenitor cells dedifferentiate, enter the cell cycle, self-renew, and have a context-dependent probability of differentiating into regionally specific differentiated cell types such as ciliated epithelial cells and ATII cells.³⁶³⁻³⁶⁶ Examples of facultative progenitor cells in the lung are the club cell in the airway and the ATII cell in the alveolus.³⁵⁶

Loss of Regenerative Potential: Depletion of the Facultative Progenitor Cell Pool

Multifunctional properties of pulmonary facultative progenitor cells also limit their ability to repair the injured conducting airway epithelium in the mouse lung. First, the metabolic pathways that allow the club cell to eliminate lipophilic agents also sensitize it to the toxic effects of these compounds.³⁶⁷⁻³⁶⁹ Second, the phenotypic plasticity that is essential to the club cell's ability to detect and eliminate pathogens may compromise the reparative functions of this cell type.³⁷⁰⁻³⁷² Finally, repeated participation in epithelial repair may deplete the mitotic potential of the facultative progenitor cell pool. Depletion of this cell type would leave the epithelium deficient in both regenerative and differentiated functions and could result in a cascade of changes that contribute to epithelial fragility through loss of cellular autocrine/paracrine protective

mechanisms, epithelial hypoplasia, and dysregulation of interactions between the epithelial, mesenchymal, and vascular compartments.

Histologic measures of a low abundance of club cells and CCSP support the concept that the facultative progenitor cell type(s) are depleted in acute lung injury and in chronic lung diseases. These studies suggest that four processes lead to depletion of this critical cell type. First, transition to a mucus-producing cell type may alter both progenitor function and cellular interactions. Within small airways of COPD patients and asthmatics, club cells undergo a metaplastic transition to a mucosecretory phenotype.³⁷³ In severe disease, both club cells and mucosecretory cell types are depleted, and the epithelium becomes hypoplastic.³⁷⁴⁻³⁷⁶ Analysis of colony-forming cells within the human bronchial epithelium demonstrated that human mucous cells are postmitotic cells.³⁷⁷ These observations suggest that hyperplasia of mucous cells, in the context of acute or chronic lung disease, is a consequence of a phenotypic transition by non-mucus-producing cells.

Second, transition of progenitor cells from a facultative to an obligate progenitor state may also lead to depletion of reparative cells. Increased epithelial proliferation in the lungs of smokers suggests an ongoing injury process and the potential for replicative senescence within the facultative progenitor cell pool.³⁷⁸ Senescent cells persist and consequently inhibit activation of the remaining reparative cells. Thus senescent cells could compromise differentiated functions while also blocking cell replacement mechanisms.

Third, entry of the facultative progenitor cell into the cell cycle is accompanied by loss of differentiated functions such as secretion of CCSP or production of surfactant. Extensive analysis of CCSP levels in acute and chronic lung disease, including COPD, suggests that differentiated functions of the facultative progenitor cells are compromised^{379,380} and that these cells are a direct target of toxic environmental agents. Thus injuries that activate facultative progenitor cells may adversely affect protective mechanisms and render the epithelium susceptible to further injury.

Finally, defects in cellular maturation may also contribute to a failure to establish the facultative progenitor cell pool or to deplete it after injury. The lung undergoes rapid and extensive maturation during the postnatal period. The maturation process is interrupted by preterm birth and associated oxygen treatment and is attenuated by postnatal exposure to environmental agents, including ozone and side-stream tobacco smoke in term infants.³⁸¹⁻³⁸³ These studies support the concept that failure to establish or maintain an appropriately sized pool of facultative progenitor cells fosters environmentally induced chronic injury and dysfunctional repair cycles characteristic of lung disease. Hypoplasia of bronchial club cells is associated with tissue remodeling characterized by hyperplasia of an alternative progenitor, the basal cell, and consequent squamous metaplasia.³⁸⁴⁻³⁸⁶ In contrast, club and ATII cells are progenitors of the bronchiolar and alveolar epithelium, respectively,^{285,305,364,366} although as mentioned earlier, bronchiolar stem cells may repopulate the alveolus,^{305,358,359,361} and an alveolar epithelial cell that expresses $\alpha 6\beta 4$ integrin, but not prosurfactant C, may function as an alveolar epithelial progenitor cell after injury.³⁶² Depletion of either of these cell

types leads to epithelial hypoplasia and remodeling of adjacent tissue compartments. Thus changes in function and/or abundance of the facultative progenitor may be the nexus for the complex pathophysiologic alterations in chronic lung diseases.

GENE-ENVIRONMENT INTERACTIONS IN LUNG INJURY AND REPAIR

The four Rs (regeneration, repair, remodeling, and replacement) are presented as distinct processes; however, they are actually intricately intertwined responses to acute or chronic lung injury (Fig. 15-6). These relationships are modified by gene-environment interactions, interactions based on the concept that genetic constitution determines the response to deleterious agents within the environment.

Genetic predisposition has been associated with allelic variants that modify cellular susceptibility to environmental agents, including chemical (ozone, naphthalene, cigarette smoke) and microbial (lipopolysaccharides, viral pathogens) agents. Such alleles can sensitize an individual to an initial or repeated injury but can also render him or her resistant to subsequent exposures through induction of tolerance.

Genotype can also be a determinant of the cellular response to an agent. In mice, specific genetic backgrounds are susceptible to metaplastic transitions such as conversion of airway secretory cells into a mucus-producing

goblet cell phenotype (e.g., C57BL/6 vs. Balb/c strains of mice). Such transitions are associated with protection of the epithelium from further injury. Alterations in cellular phenotype may also extend to interactions between endogenous lung elements (epithelium, mesenchyme, nerves) and itinerant (recruited) cells such as neutrophils, monocytes, and lymphocytes. Certain inbred strains of mice (e.g., C57BL/6) are more susceptible to bleomycin-induced inflammation and develop transient replacement of alveolar structures with mesenchymal cells resulting in fibrosis. Thus susceptibility to injury and the response to such an insult are determined by multiple factors, including the nature of the agent, dose and route of exposure, exposure history, the host genotype, and epigenetic factors molded by gene-environment interactions.

DOES LUNG REPAIR RECAPITULATE LUNG DEVELOPMENT?

Numerous signaling processes are known to be involved in lung development including Wnt/ β -catenin, notch-delta, sonic hedgehog-patched, fibroblast growth factor–fibroblast growth factor receptor, and bone morphogenetic protein/TGF- β .³⁸⁷ These pathways are interactive and integrate formation and appropriate differentiation of tissues (epithelium, mesenchyme, vasculature) during lung development. During lung injury and repair, reactivation of many of these pathways has been reported. It is unclear, however, whether these various signaling pathways are integrated and whether this signaling results in productive cell replacement. Indeed, analysis of damaged human lung tissue is descriptive, and thus cause and consequence usually cannot be separated. In contrast, analysis of signaling pathways in animal models relies on elimination of a specific pathway or profound misregulation of the targeted process. Consequently, feedback mechanisms are likely to be disrupted and may result in altered activation/inactivation of parallel or sequential signaling networks. Development of methods to simultaneously monitor alterations in multiple signaling cascades is needed to address this fundamental obstacle to understanding the molecular regulation of reparative processes. Hence at this time it is not known if regulatory pathways that are dominant during development also regulate repair in the adult.

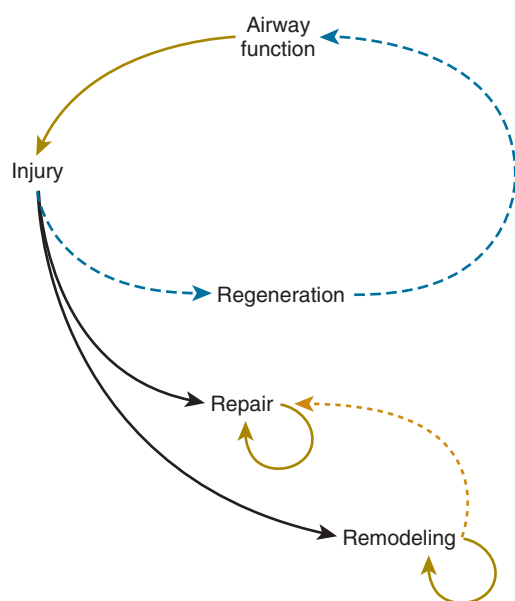

Figure 15-6 Gene-environment interactions in lung injury, regeneration, repair, and remodeling. The four Rs (regeneration, repair, remodeling, and replacement) are presented as distinct processes; however, they are actually intertwined responses to acute or chronic lung injury. These relationships are modified by gene-environment interactions, interactions based on the concept that genetic constitution determines the response to deleterious agents within the environment. (Adapted from Lazaar AL, Panettieri RA Jr: Is airway remodeling clinically relevant in asthma? *Am J Med* 115:652–659, 2003.)

Key Points

- The processes of lung injury and repair underpin the pathogenesis of myriad lung diseases, as well as the normal aging process.
- The mechanisms of injury are rooted in the cellular and molecular changes that initiate structural alterations and lead to compromised lung function. At the tissue and cellular level, exogenous insults and/or inflammatory stimuli result in increased vascular permeability and loss of alveolar epithelial barrier function due to disruption of intercellular junctions and cell death.

- Susceptibility to lung injury is determined by general health, previous exposures, and the individual's genetic constitution. This “gene-environment interaction” is the cornerstone of research initiatives directed at identification of susceptibility genes and those that modify the response to treatment.
- Lung repair involves restoration of normal cellular composition, lung architecture, barrier function, and gas exchange.
- In response to cellular injury by noxious stimuli such as microbes and toxic compounds, endogenous stem and progenitor cells undergo rapid proliferation and differentiation resulting in repair and regeneration of the injured lung. Under normal circumstances repair of the alveolar epithelium after injury depends on cell spreading, migration, and proliferation of surviving *alveolar epithelial type II* (ATII) cells, followed by differentiation of ATII cells into ATI cells. However, in severe injury, additional non-surfactant protein C-expressing cells, likely from the bronchioalveolar junction, can repopulate the alveolar epithelium.
- Repetitive epithelial injury and dysfunctional repair can lead to fibroproliferative responses in the airways and parenchyma; fibroproliferative responses are thought to be critical to the pathogenesis of some diseases, including pulmonary fibrosis, COPD, and asthma.
- Ultimately, the inflammatory response must resolve in order to halt ongoing injury to the lung and to allow repair. Inflammatory cells undergo apoptosis and are cleared by macrophages in a phagocytic process termed “efferocytosis.”

Extrapulmonary Manifestations

INTRODUCTION

Taking a careful and complete history and performing a thorough physical examination are hallmarks of the good internist and one of the distinguishing characteristics of a master clinician. The initial visit sets the tone of the immediate and future relationship with the patient and begins the process of diagnosing and managing the illness; it is a dynamic encounter, with each of the patient's responses stimulating further probing and forming of diagnostic hypotheses. The physician must be attentive to the patient's story, piecing together each bit of evidence to form a tentative preliminary diagnosis and differential diagnoses. Nothing should escape the eyes and ears of a watchful diagnostician. History taking is more than information gathering; it affords the opportunity to decipher the patient's body language as the inquiry proceeds. At this stage, no symptom or circumstance should be disregarded. With an understanding of biology and medicine coupled with past experience, the physician tries to connect the salient parts of the patient's story to develop a plausible explanation of the physiologic or pathologic events that lead to illness.

Although striving for a single diagnosis, the physician should realize that more than one disease may be present and that rare diseases are diagnosed only by those who consider them. Nevertheless, the maxim "uncommon presentations of common diseases are more frequent than common presentations of uncommon diseases" is likely to be true. It is important to continue both to gather information and to be open to reforming the diagnostic hypothesis

as more information becomes available. Premature judgment or the failure to continue considering reasonable alternatives after an initial diagnosis is made is the single most common diagnostic error.^{1,2} In the field of decision science, these failures are postulated to arise from "cognitive dispositions to respond" and include several of the biases in judgment or reasoning defined in [Table 16-1](#).³ It is hypothesized that a greater awareness of these prejudices among clinicians may facilitate "cognitive debiasing," thereby reducing the frequency of these common errors of reasoning.⁴ An alternative or potential complementary approach is to use decision-support software to expand the differential diagnosis and avoid overlooking unusual or severe conditions.⁵

Bayes theorem implies that diagnostic tests will have a higher yield if the prior probability of the diagnosis is high (also called pretest probability). Specific details from the history raise the probability of different diagnoses and direct further tests in a productive manner. Further diagnostic investigations—imaging, blood tests, pulmonary function studies, and even parts of the physical examination—depend on the history. Historical clues raise or lower probabilities, thereby improving the value of subsequent questions and evaluations. Test results plus findings from the history and physical examination may confirm or refute the main and differential diagnoses, setting up either a management plan or the need for an alternative hypothesis.

At the end of the initial evaluation, the assessment and plan should identify problems and a course of action that

Table 16-1 Selected Biases in Judgment or Reasoning

Bias	Definition
Anchoring	Tendency to lock onto salient features in the patient's initial presentation too early in the diagnostic process, and failing to adjust this initial impression in light of later information.
Confirmation bias	Tendency to look for confirming evidence to support a diagnosis rather than to look for evidence to refute it, despite the latter often being more persuasive and definitive.
Framing effect	Tendency to be strongly influenced by how the problem is presented (e.g., perceptions of risk to the patient strongly influenced by whether the possible outcome is expressed in terms of the possibility that the patient might die or might live).
Premature closure	Tendency to accept a diagnosis before it has been fully verified. The consequences of the bias are reflected in the maxim "When the diagnosis is made, the thinking stops."
Search satisfying	Tendency to call off a search once something is found. Comorbidities, second foreign bodies, other fractures, and coingestants in poisoning may all be missed. Also, if the search yields nothing, diagnosticians should satisfy themselves that they have been looking in the right place.
Unpacking principle	Failure to elicit all relevant information (unpacking), which may result in missing significant diagnostic possibilities.

takes into account the patient's concerns and questions. The patient should feel satisfaction that the physician has done a thorough job of exploring his or her complaints, has provided a plausible explanation for them, and has planned a reasonable course of action.

ELECTRONIC DOCUMENTATION

The electronic medical record now allows documents of higher quality than written records, owing to improved organization, increased readability, use of supplementary material, and better comparisons. It eliminates poor handwriting and lost or misplaced information. Additional benefits include cost savings for storage, easy accessibility, and quick transfer to another health care provider.⁶ The electronic medical record facilitates a coordinated team approach and reduces duplication of tests. Patients with complicated illnesses often have several different physicians, and electronic records can make it easier for one team to follow what another team is doing. Easy access to a complete record is especially important in emergency situations for physicians who are unfamiliar with the presenting patient. Electronic medication lists and reminders can save time and reduce errors. Electronic prescriptions provide greater patient safety.

Writing directly into the medical record, or initially through a word processing program, makes a cogent summary and chronological story easier to produce. The ability to insert information where it belongs helps maintain a congruous timeline. Spelling and grammar checks and autocorrection of abbreviations should make the finished report an easily readable document.

The disadvantages of electronic medical records include "information overload" and potential loss of privacy. Software downtime can be crippling. Learning how to use specific applications and developing typing skills may require training. Most word processing software used in electronic medical records is less efficient than commonly used commercial word processing software.

The "cut-and-paste" technique, beginning where the last visit left off, both saves time and ensures that ongoing problems are not overlooked. The problem with the cut-and-paste approach is that too much information may get deposited and duplicated in the medical record, including information irrelevant to the purpose of the consultation. Such excess text can at times replace essential information and impair easy understanding and critical reasoning. Cutting and pasting of information from consultants and other involved persons should never substitute for one's own primary history gathering or clinical thought. Cutting and pasting information gathered by someone else implies agreement with the statements. Proofreading is essential, especially of electronic prescriptions, because of the different doses and means of delivery of certain drugs.

Transfer of electronic medical information is not foolproof. Patients and physicians find it easy and convenient to communicate and transfer information by email, but there is a risk that the record of these interchanges may fail to be placed in the patient's permanent medical record, be intentionally or unintentionally intercepted leading to loss of privacy, or otherwise cause misunderstanding. Physicians may send patients electronic copies of their record, but if these are in a word processing format, patients could alter the record for secondary gain. Many of these concerns could have medicolegal consequences.⁶

COMMUNICATION SKILLS

The ability to listen skillfully, and to communicate clearly and empathetically with the patient, is the foundation for the physician-patient relationship. Communicating effectively with patients and peers underlies the success of a physician. The physician's communication should be objective, nonjudgmental, and empathic. Physicians are often better at obtaining medical information than they are at understanding how that information affects the patients.⁷ Communication contains both verbal and nonverbal interactions.⁸ A calm atmosphere, relaxed setting, and ample time are essential, particularly when disclosing bad news,⁹ but even then, a physician with good communication skills should be able to make the patient pleased that she or he saw the physician. This can be accomplished by always stating the truth but by cushioning ominous information with hope. When realistic, the physician might say, for example, that the cancer was caught early, provide reassurance about a probable good outcome, or suggest a new and improved therapy.

The old-fashioned tutorial approach of learning how to be a good physician had many shortcomings; students, residents, and fellows learned medicine as apprentices in "a catch-as-catch-can" manner. More recently, however, scientific testing and social psychological analysis have uncovered egregious flaws in how physicians obtain, sort out, and

evaluate diagnostic information. Sir William Osler used to tell students to “listen to the patient, he (or she) will tell you the diagnosis.” Today—instead—as Dr. J. Groopman points out in his excellent book, *How Doctors Think*, physicians interrupt the patient’s initial history in just 16 seconds and frequently thereafter, make snap judgments, and fall into cognitive traps that are much more likely than factual ignorance to lead to medical errors.¹⁰ New practice guidelines from evidence-based research help steer a correct diagnostic course, but the presence of overlapping diagnoses, unusual symptoms, and uncommon diseases requires wise and discerning physicians, not inflexible algorithms.

MEDICAL INTERVIEW

There is much more to the medical history than a recitation of questions and recording of answers. Instead, the medical interview has been defined as the entire medium of patient-physician interaction.¹¹ From this interactive experience, both physicians and patients learn about each other: the knowledge shared and feelings imparted influence subsequent trust, understanding, concern, and adherence to the health plan. Experience is valuable in the acquisition of clinical pattern recognition and in accumulating clinical knowledge. Although interviewing skills can be systematically learned,¹² acquiring the art of adept history taking and physical examination is a lifelong process that is incrementally improved by careful practice.

The main purposes of the medical interview are to (1) gather useful information, (2) develop rapport, (3) respond to concerns, and (4) educate the patient. The ease with which patients can access medical information may lead to a more active role on their part; patients may be well informed or misinformed about their actual or perceived diagnoses. Whatever their knowledge, most patients want to be accurately informed about their condition and to be involved in the deliberations and decision making.¹³ At the same time they generally want their physician to direct their health care in a reasoned manner, which entails taking into account the patients’ background knowledge, prejudices, and culture in a sensitive manner. This means the physician’s plan should take into account the individuality of the patient.

Encouraging the patient to take the lead in expressing his or her symptoms and relationships to these symptoms forms the basis for the patient-centered interview¹⁴ and develops appropriate rapport. Even in this era of reliance on laboratory studies, Platt’s original claim¹⁵ that a diagnosis can be obtained by history taking alone in most patients has been reaffirmed by several subsequent investigations.¹⁶⁻¹⁸

CHIEF COMPLAINT AND PRESENT ILLNESS

The medical history has traditionally been subdivided into the chief complaint; present, past, family, and social histories; and systems review. Because of its relevance and importance in the evaluation of patients with known or suspected pulmonary diseases, the occupational history is included as a separate component of the social history. Travel history, also included in the social history, is helpful in diagnosing certain lung diseases.

Only the chief complaint stands alone as a discrete response to a single question. It is generally recommended that the chief complaint be written in the patient’s own words, lest the physician’s interpretation be substituted prematurely for the patient’s unique concern. Each chief complaint must be explored in detail, and the resulting aggregate of information constitutes the history of the present illness. The various elements of the remainder of the history are sorted into their proper categories after the interview has been completed. The resulting history of present illness is a cogent chronological story that incorporates all the facts and their relationships that support the preliminary diagnosis and differential diagnoses. Although an open-ended and free-flowing encounter, the interview still should be focused and organized. Each new question is often linked to the answer to the previous one. At the end the review of systems is a series of questions designed to cover previously unexamined territory.

Even as the clinician fulfills the roles of information gatherer and detective, a more complex process is occurring in which a patient’s verbal and nonverbal responses to symptom queries provide a personal and often explanatory narrative that may encapsulate unique and individual aspects of illness. These may include the experience of illness and its relationship to any and all aspects of the patient’s life. The emerging field of narrative medicine highlights the effects such storytelling has on patients and providers, and its ability to enrich the physician-patient relationship and the clinical experience.^{19,20}

MAJOR PULMONARY SYMPTOMS

Because dyspnea, cough, and chest pain are among the most common reasons for patients to visit physicians, and because these symptoms may result from serious underlying chest disease, careful questioning is needed to establish their etiology and significance. The anatomic and pathophysiologic basis of these cardinal symptoms is provided in Chapters 29 to 31. To aid the interviewer in obtaining a medical history, a brief overview of these three common presenting symptoms and a related one, hemoptysis, is provided in this section.

Dyspnea

When a healthy person increases his or her level of physical activity sufficiently, an awareness of breathing emerges; if the severity of activity increases even further, the sensation becomes progressively more unpleasant, until it typically compels the individual to slow down or stop.²¹ Although dyspnea, shortness of breath, and breathlessness are often used interchangeably, as in Chapter 29, some purists use the term *dyspnea* only when the symptom is abnormal, which implies that the awareness is disproportionate to the stimulus and that the sensation is pathologic. Many patients describe their breathing discomfort as “breathlessness,” but many others complain of “tightness,” “choking,” being “unable to take a deep breath,” “suffocating,” being “unable to get enough air,” or occasionally even “tiredness.”

The mechanisms that underlie the sensation of dyspnea remain poorly understood and are reviewed in Chapter 29. In contrast to pain and cough, for which specific receptors and neural pathways have been identified, similar detailed

knowledge is lacking for dyspnea, although evidence is mounting that links the symptom with pain.^{21,22} Studies of the neurophysiology of dyspnea are further complicated by the lack of objective tools to quantify a subjective sensation with interindividual variation. Rating instruments—such as the Borg scale²³ and questionnaires, such as the British Medical Research Council questionnaire²⁴ and Pulmonary Functional Status and Dyspnea Questionnaire²⁵—have been validated as useful in measuring dyspnea. Self-administered, computerized versions of the Transitional Dyspnea Index and Multidimensional Baseline Dyspnea Index appear to be at least as good as interview questioning for this assessment.²⁶ Progress, though, is being made: recent studies have clearly shown that dyspnea during exercise in patients with *chronic obstructive pulmonary disease* (COPD) is closely linked to dynamic lung hyperinflation.²⁷

Clinical Features. Patients with respiratory, cardiac, hematologic, metabolic, and neuromuscular disorders may all complain of dyspnea. A careful and detailed history is necessary to uncover the cause of the sensation. In addition, it is important to document the impact of the symptom on the patient's daily activities and to be alert to the "decreased activity phenomenon." The latter describes patients who say their dyspnea has not worsened, but only because they now walk more slowly or no longer climb stairs or engage in athletic activities. Sometimes this slowing down is so gradual, patients may be unaware or attribute it to aging. Assessing the activity required to bring about the dyspnea is important. How many stairs can be climbed before stopping? How far can someone walk on level ground at her or his own pace without stopping? Does talking on the phone, getting dressed, or eating cause dyspnea? Is the patient short of breath at rest?

The course over time should be noted. Sudden dyspnea without an obvious provocation suggests pulmonary embolism or pneumothorax, although myocardial ischemia and asthma also may have a rapid onset. Dyspnea caused by cigarette smoke, dusts, molds, perfumes, newly cut grass, cats, and strong odors is characteristic of the increased bronchial reactivity seen in asthma. Associated features, such as wheezing and the presence and type of chest tightness or pain, are important clues. Worsening dyspnea with cough producing increased quantities of purulent sputum over 1 to 3 days characterizes an exacerbation of COPD.

Special types of dyspnea are sufficiently distinctive to warrant separate designations. Episodes of breathlessness that wake persons from a sound sleep, *paroxysmal nocturnal dyspnea*, usually denote left ventricular failure but may also occur in patients with chronic pulmonary diseases because of pooling of secretions, gravity-induced decreases in lung volumes, sleep-induced increases in airflow resistance, or nocturnal aspiration. *Orthopnea*, the onset or worsening of dyspnea on assuming the supine position, like paroxysmal nocturnal dyspnea, is found in patients with heart disease and chronic lung disease. Measurement of amino-terminal pro-B-type natriuretic peptide has proved useful in differentiating between a cardiac and a respiratory origin in patients with dyspnea.²⁸

The inability to assume the supine position (*instant orthopnea*) is characteristic of paralysis of both leaves of the diaphragm. Dyspnea soon after assuming the supine

position also may be associated with other conditions, such as arteriovenous malformation, bronchiectasis, and lung abscess. *Platypnea*, which denotes dyspnea in the upright position, and *trepopnea*, an even rarer form of dyspnea that develops in either the right or the left lateral decubitus position, suggest lung vascular shunting. Both the terms *hyperpnea*, an increase in minute ventilation, and *hyperventilation*, an increase in alveolar ventilation in excess of carbon dioxide production, indicate that ventilation is abnormally increased. Neither term, however, carries any implication about the presence or absence of dyspnea.

Cough

The quantity of bronchial secretions produced each day by a nonsmoking healthy adult is not precisely known, but it is sufficiently small to be removed by mucociliary action alone: healthy persons seldom cough.²⁹ As described in Chapter 30, coughing is an essential mechanism that protects the airways from the adverse effects of inhaled noxious substances and defends the lungs by clearing excess secretions.³⁰ Coughing can be occasional, transient, and unimportant. By contrast, it may indicate the presence of severe intrathoracic disease.

Clinical Features. Most episodes of coughing are associated with short-lived upper respiratory tract infections or allergies, and patients, recognizing this, seldom visit their physicians for this type of cough. Nevertheless, cough is the most common complaint for which patients seek medical attention and the second most common reason for having a general medical examination.³¹ Physicians should realize that when patients seek their help for cough, it is often out of concern for something new, different, and alarming about the symptom. The essential first step in evaluating a patient with cough is to obtain a thorough history, paying particular attention to the following aspects: acute or chronic, productive or nonproductive, character, time relationships, type and quantity of sputum, and associated features. It is noteworthy that, of the various components of the workup used by the authors of a systematic anatomic investigation to determine the causes of chronic cough, the medical history alone led to the correct diagnosis in 70% of patients.³¹

Acute coughing is frequently associated with nasopharyngitis, laryngotracheobronchitis, or other, usually virus-induced, upper respiratory tract infections. Less commonly, it may be the chief manifestation heralding the onset of viral or bacterial bronchopulmonary infection or the inhalation of allergenic or irritating substances. The causes of cough that persisted for 3 weeks or longer in 102 patients were postnasal drip (41%), asthma (24%), gastroesophageal reflux (21%), chronic bronchitis (5%), and bronchiectasis (4%).³¹ Other important though less common conditions include eosinophilic bronchitis³² and the use of angiotensin-converting enzyme inhibitors.³³ In 1999 the importance of the "big three"—postnasal drip, asthma, and gastroesophageal reflux—was verified by the results of another survey of the causes of chronic cough.³⁴ Not everyone agrees, however, and some experts claim that emphasis on the top three conditions is unwarranted and moreover that it stifles interest and research into other important causes and mechanisms of chronic cough.³⁵

A careful history of patients with cough lasting at least 3 months revealed that nearly all the patients misdiagnosed as “psychogenic” had one of the conditions listed previously for chronic cough.³⁶ Even cough that is made worse with psychological stress is often caused by underlying lung disease. Patients with exaggerated cough responses or habitual cough may have a “psychogenic” component; therefore, even when chronic cough has a pulmonary cause, it may respond to behavioral modification.³⁷

Most physicians have heard the ancient diagnostic axiom, which is still true, that any change in the character or pattern of a chronic cough in a smoker demands a prompt chest radiographic evaluation for lung cancer. Less well known is that cough may be the sole presenting manifestation of asthma³⁸ or gastroesophageal reflux disease.³⁹

In low-income countries, where the majority of the global population lives, cough, usually productive but not always, of 3 weeks or longer has been the traditional (and reliable) clinical marker of possible pulmonary tuberculosis that should trigger examination of sputum specimens for *Mycobacterium tuberculosis*. Revised recommendations by tuberculosis experts now include cough of “2 or 3 weeks,” or longer, as an indication for sputum examination.⁴⁰

Among the many complications of persistent or recurrent cough are tussive syncope; retinal vessel rupture; persistent headache; chest wall and abdominal muscle strains, including the development of abdominal wall hernia⁴¹; and even rib fractures. Severe chronic cough may create devastating personal distress, causing patients to restrict their social and professional activities.

Hemoptysis

The expectoration of any amount of blood denotes hemoptysis. Every patient with new-onset or appreciable hemoptysis deserves a thorough diagnostic evaluation, which generally includes *computed tomography* (CT) of the thorax and bronchoscopy. For centuries, hemoptysis was considered pathognomonic of pulmonary tuberculosis, a view that is summarized in the Hippocratic aphorism “the spitting of pus follows the spitting of blood, consumption follows the spitting of this, and death follows consumption.”⁴² The frequency of the different conditions that cause hemoptysis depend to a large extent on the population studied, but bronchitis, lung cancer, tuberculosis, and bronchiectasis are usually the most common causes.⁴³⁻⁴⁵ These are also the leading causes of massive hemoptysis (defined in various series as >200 or >600 mL of blood in 24 hours). Lung cancer and bronchitis usually cause mild to moderate bleeding, whereas patients with bronchiectasis, lung abscess, fungal disease, or a bleeding diathesis are more likely to have severe bleeding.⁴³ Less common conditions associated with hemoptysis include arteriovenous malformations, broncholithiasis, foreign bodies, aspergilloma, mitral stenosis, trauma, excessive anticoagulation, pulmonary hemorrhage syndromes, heart failure, pneumonia, and granulomatosis with polyangiitis (Wegener granulomatosis).

Clinical Features. Prompt evaluation, beginning with a thorough history, is required in all patients. It is important to determine where the blood is coming from. Surprisingly, patients may not always be able to distinguish hemoptysis from hematemesis and nasopharyngeal bleeding. Vomiting

blood may follow a prolonged coughing episode. Patients may swallow or aspirate blood from the upper airway. Some patients report only that the blood “welled up” in their throats. Others will say that it is mixed with sputum. Hematemesis can usually be differentiated from hemoptysis by the presence of symptoms of gastrointestinal involvement, such as nausea and vomiting, a history of peptic ulcer disease, alcoholism, or signs of cirrhosis; when in doubt, esophagoscopy is indicated.

Following physical examination, a chest radiograph and (often) a chest CT are required. Depending on the magnitude of the blood loss and the clinical circumstances, bronchoscopy is indicated to determine the location of the bleeding. Although these studies generally reveal which region of the lungs is the source, the cause of hemoptysis cannot be determined in 20% to 30% of cases.⁴⁶ Recent radiologic advances, which enhance identification of the culprit vessel, particularly multidetector computed tomographic angiography, have greatly helped the interventionist when bronchial artery embolization is required to stop the bleeding.⁴⁷

Chest Pain

Various types of chest pain are extremely common; their mechanisms and clinical patterns are described in Chapter 31. Chest pain is one of the most common symptoms that cause the sufferer to seek medical attention. Because there is no clear relationship between the intensity of the discomfort and the importance of its underlying cause, all complaints of chest pain must be carefully considered. The recent development of dedicated chest pain centers within emergency departments has improved the accuracy and rapidity of diagnosis, the treatment, and the survival of patients with this always troublesome symptom.⁴⁸

Clinical Features. Pleurisy, or acute inflammation of the pleural surfaces, has several distinctive features. Pleuritic pain is usually localized and unilateral—and tends to be distributed along the intercostal nerve zones. Pain from diaphragmatic pleurisy is often referred to the ipsilateral shoulder and side of the neck. The most striking and defining characteristic of pleuritic pain is its clear relationship to respiratory movements. The pain may be variously described as “sharp,” “burning,” or simply “a catch,” but it is typically worsened by taking a deep breath, and coughing or sneezing causes intense distress. Patients with pleurisy frequently also experience dyspnea because the aggravation of their pain during inspiration makes them conscious of every breath.

Acute pleuritic pain is found in patients with spontaneous pneumothorax, pulmonary embolism, and pneumonia, especially pneumococcal pneumonia, whereas a gradual onset over several days is observed in patients with tuberculosis; an even slower development is characteristic of primary or secondary malignancies. Chronic pleuritic pain is characteristic of mesothelioma. It may be difficult to distinguish pleuritic pain from the pain of a rib fracture, although point localization favors the latter. Pericardial pain is typically sharp, retrosternal in location, and relieved by sitting up and leaning forward.

The distribution and the superficial, knifelike quality of the pain of intercostal neuritis or radiculitis may resemble

pleural pain because it is worsened by vigorous respiratory movements but, unlike pleurisy, not by ordinary breathing. A neuritic origin may be suggested by the presence of lancinating or electric shock–like sensations unrelated to movements, and hyperalgesia or anesthesia over the distribution of the affected intercostal nerve provides confirmatory evidence. In many instances of new-onset, neuritic chest wall pain, the diagnosis becomes clear a day or two later when the typical vesicular rash of herpes zoster appears.⁴⁹

Among the most important types of chest pain is myocardial ischemia, which is usually caused by coronary artery atherosclerosis. These attacks, which are provoked by inadequate oxygen delivery to the myocardium, span a continuum of severity from chronic stable angina to classic acute myocardial infarction. Typical anginal pain is induced by exercise, heavy meals, and emotional upsets; the pain is usually described as a substernal “pressure,” “constriction,” or “squeezing” that, when intense, may radiate to the neck or down the ulnar aspect of one or both arms.⁵⁰ Pain from variant or Prinzmetal angina is similar in location and quality to typical anginal pain but is experienced intermittently at rest rather than during exertion.⁵¹ Both typical and variant types of angina are relieved by coronary vasodilator drugs, such as nitroglycerin. Typical angina also decreases with rest or removal of the inciting stress.

By contrast, the pain of acute myocardial infarction, although similar in location and character to anginal pain, is usually of greater intensity and duration, is not alleviated by rest or by nitroglycerin, may require large doses of opiates, and is often accompanied by profuse sweating, nausea, hypotension, and arrhythmias. During attacks of myocardial ischemia and myocardial infarction, patients are often short of breath from associated pulmonary edema, which may be severe, but the pain itself is not related to breathing. Pain similar to that of myocardial ischemia also occurs in patients with aortic valve disease, especially aortic stenosis, and other noncoronary heart disease and extracardiac disorders.

Inflammation of or trauma to the joints, muscles, cartilages, bones, and fasciae of the thoracic cage is a common cause of chest pain.⁵² Redness, swelling, and soreness of the costochondral junctions is called Tietze syndrome. All of these disorders are characterized by point tenderness over the affected area.

Most pulmonary thromboemboli are not associated with chest pain; the hallmark of pulmonary infarction, however, is typical pleuritic pain. Both acute and chronic causes of pulmonary hypertension may be associated with episodes of chest pain that resemble the pain of myocardial ischemia in its substernal location and pattern of radiation and in its being described as “crushing” or “constricting.”⁵² This type of chest pain is believed to result from right ventricular ischemia owing to impaired coronary blood flow secondary to increased right ventricular mass and elevated systolic and diastolic pressures or to compression of the left main coronary artery by the dilated pulmonary artery trunk.

FAMILY HISTORY AND SOCIAL HISTORY

The family history provides important clues to the presence of heritable pulmonary diseases, such as cystic fibrosis, α_1 -antitrypsin deficiency, hereditary hemorrhagic

telangiectasia (Osler-Weber-Rendu disease), immotile cilia syndrome, and immunodeficiency syndromes, among others. Careful history taking also can uncover even more common familial disease associations, which are polygenic or in which the exact mode of genetic transmission has not yet been established. As genomic surveillance is uncovering more and more genetic linkages, the family history assumes an even more important function. The family history should encompass at least three generations to account for sex-linked traits. Family history also can identify exposures such as to tuberculosis or other contagious diseases.
